THE TREATMENT OF SIMPLE CASES OF DIABETES*

ARCHIE H. BEARD, M.D.

Assistant Professor of Medicine, University of
Minnesota

Minneapolis

In order to appreciate better the use of insulin in the treatment of diabetes mellitus without complication, we should first review the dietary progress made in the disease during the last few years. Certain fundamental principles have been laid down which have increased our success. Unless these facts are considered in our treatment, insulin will not receive the result that it deserves. There are four main principles to be reviewed.

In the last few years although there has been a reaction against extreme undernourishment established in Allen's and in Joslin's important works in relation to total dietary restriction, yet we must never forget the important step these men took in this disease. In the end, Allen's and Joslin's work has left one necessary factor to consider, namely, the limit of total calories necessary for body maintenance for the individual.

Joslin reported that before 1914 diabetic patients usually had a higher basal metabolic rate than normal individuals of the same height and weight. After Joslin's routine had been established he found the rate below the standard selected by Benedict and Joslin. Later Allen verified this work in thirty-six patients which he studied. Both men felt that the two chief factors that governed the increased rate were diet and acidosis. Works by other men have not agreed entirely with these statements. If the patient is well nourished, and secondary factors, as infection, hyperthyroidism, high protein and caloric diets, can be eliminated, a higher rate than normal does not necessarily occur.

We realize also that acidosis under even lax diabetic supervision is usually more or less dependent on the same secondary factors as mentioned above. Out of this work, however, has emerged one definite idea, namely, that with the proper restriction of protein the metabolic rate can be brought below or even to normal, and thereby a diabetic patient can be made to burn his caloric intake or body tissues at a level more compatible to dietary restriction.

The second principle, namely protein restriction, has been developed from the work established out of the above results. A few years ago the physiologists were shocked when the clinician suggested the use of only one gram of protein per kilogram body weight in diabetic individuals. Newburgh and Marsh, however, suggested two-thirds of a gram of protein, and later Wilder and Boothby found that high protein intake definitely increased body metabolism in this disease. From this work it has been found that two-thirds of a gram of protein will generally maintain the adult patient in nitrogenous equilibrium. Today we also recognize that 58 per cent of the protein in the diet can be burned as glucose, which in the end may embarrass the body in its attempt to burn carbohydrates. In order to attain the low protein intake, however, and still maintain a nitrogenous balance the total caloric needs of the patient must be watched. Because of this fact, Newburgh and Marsh had their good results with the so-called high fat diet.

The third principle is based on clinical evidence, namely, that the pancreas should attempt to handle only the amount of carbohydrates that is below the glucose tolerance of that patient. This, of course, varies with each individual diabetic, but after a carbohydrate tolerance has been established, it is well to keep below that level, for by so doing, the pancreas is more apt to recuperate and return to a higher point of efficiency. In other words an over-worked engine is more apt to break under the strain than one which is not held at its full capacity at all times.

*Presented in symposium before the Annual Meeting of the Minnesota State Medical Association, St. Paul, October, 1923.

The fourth principle is the result of Woodyatt's opposition to Allen's idea that marked restriction of fats was necessary to keep a diabetic patient away from acidosis and coma. Woodyatt felt that fats could be used as long as a definite molecular ratio was kept between the fatty acid and glucose. This idea was later proven clinically by Newburgh and Marsh and also by Shaffer in his experimental work. Shaffer found that it was necessary to have one molecule of glucose present in order to burn two molecules of fatty acid and thereby helped to develop an old statement of Joslin's that "fat burned better in the flame of carbohydrates." From this work has developed the principle of balancing the ketogenic (fatty acid) and antiketogenic (glucose) molecules in the diet. Usually one and a half to one relationship as suggested by Woodyatt is the best basis of safety.

Many charts have been devised as a short cut using the above principles in our dietary routine. They are all based in some way on this work, but it is worth while to review the formulae used in computing the proper balance of carbohydrates, protein and fat. In the end all food of a diet except a small fraction of the protein is broken down into two elements, namely, glucose and higher fatty acid. We know that

100 grams of carbohydrates give 100 grams of glucose and no fatty acid;

100 grams of protein give 58 grams of glucose and 46 grams (?) of fatty acid;

100 grams of fat give 10 grams of glucose and 90 grams of fatty acid, if burned in the body.

Therefore in the diet

Glucose=100 per cent carbohydrates plus 58 per cent protein plus 10 per cent fat;

Fatty acid=0 per cent carbohydrates plus 46 per cent protein plus 90 per cent fat.

With these formulae and keeping in mind the ratio of fatty acid to glucose, which will give the proper combustion, we can follow the principles mentioned above. It is necessary to remember that diabetic patients are better on a restricted diet than a higher caloric intake, and to add to this the fact that the metabolic rate can be controlled at a lower level if only two-thirds of a gram of protein is used for each kilogram body weight.

Wilder and Boothby have printed a very good chart for this work, and there have been a few developed by other men. These can be used very easily by the clinician, but he should never forget

the basis of the work, namely, a lowering of the metabolic rate without loss of body tissue; low protein; low carbohydrates; and a safe ratio between the ketogenic and antiketogenic substances. These diets are generally called "low maintenance diet." Starvation as used by Allen originally is rarely necessary under this regime.

We can better understand the use of insulin in these patients if we keep in mind the principles mentioned above. Insulin in its preparation and standardization is not to be covered in this article. Due to the courtesy of the Toronto investigators and Eli Lilly, we were able to get a supply of iletin, the name given by Lilly to their preparation. Today we are using it in the University Hospital with splendid results. Because of the limited time we will not report the early results and difficulties encountered in this work. The standardization of this material is nearly perfected at this time and the indications and results will be covered in other articles.

Probably the best method of covering the treatment in uncomplicated diabetes is by reporting typical cases.

A female patient (No. 25960 U. H.), height 5 feet 2 inches, aged 59, had had diabetes for a year. The symptoms had been typical, and she had lost 30 pounds in weight. Six months ago the patient became discouraged and since that time had only restricted the carbohydrates moderately. There was a strongly positive diacetic and sugar reaction and on the day of admission to the hospital the laboratory reports showed a blood sugar of .40 per cent and a plasma dioxide combining power of thirty-six mm. of mercury. The basal maintenance diet was 1,170 calories. It was given as 16 grams of carbohydrates, 28 grams of protein and 115 grams of fat. This diet was continued for three days, and the diacetic test on the urine became negative. On the sixth day the patient was still showing 10 grams of sugar in the urine. On the seventh day starvation, as used under the old regime, was given, and the next day the patient was sugar free. Another day of starvation was allowed since the blood sugar still remained .20 per cent. On the following day we gave the former diet. After six days the patient was still sugar free, and the carbohydrates were increased 10 grams a day until the patient received 76 grams of carbohydrates. Glycosuria developed at this point, and therefore the diet was continued for six days showing an average of 10 grams of glucose excretion daily. Because of the inability of the patient to remain on a low diet in comfort, we decided to give 5 units of iletin to care for the excess of glucose excretion. Therefore the glucose tolerance for this instance would be 110 grams, according to Woodyatt's formulae. Taking this amount of glucose and returning to our relationship, which we wish to keep between the fatty acid and glucose, of one and a half to one gram of each, we are allowed 163 grams of fatty acid, and therefore the diet

should be carbohydrates 76 grams, protein 28 grams, and fat 143 grams. We usually allow the patient to leave the hospital on one gram of protein, if possible, and therefore the patient was later given a diet of carbohydrates 76 grams, protein 42 grams, and fat 115 grams, or a total caloric diet of 1,500 calories. Under this routine there was only a trace of sugar in the urine. Later a higher relationship of fatty acid to glucose was thought safe, and the patient was discharged on the following regime: carbohydrates 76 grams, protein 42 grams, and fat 200 grams, or nearly 2,400 calories. She was receiving five units of iletin daily.

The second case (No. 25734 U. H.) illustrates a more severe case in which the acidosis and glycosuria were more obstinate. The patient stated that he had been living on carbohydrates 25 grams, protein 50 grams, and fats 100 grams daily for a month. He stated that he had been excreting between 15 to 20 grams of glucose daily on this diet. For this reason and due to the fact that his blood sugar was .30 per cent and carbon dioxide combining power 25 mm. of mercury, it was thought best to watch his progress for a few days. Since we found that he showed a daily average of 28 grams of glucose excretion, we decided to place him on a basal maintenance diet of 1,700 calories. He was thirty-seven years old, weighed 145 pounds, and was 5 feet 10 inches in height. The distribution of his diet was carbohydrates 24 grams, protein 42 grams, and fat 153 grams. He was allowed to remain on this diet for eight days and was still showing a daily average excretion of 20 grams of glucose. The diacetic acid test was only faintly positive. On the above diet the glucose intake was 64 grams, but there were 20 grams of glucose excreted. Therefore, his tolerance was only 44 grams. As we thought from previous experience that a fast day would be of little value, we gave iletin to compensate for the 20 gram excretion, allowing 10 units of it a day. This was continued for a week and the glucose excretion fell to only 5 grams daily. We thought best at this time to restrict the amount of iletin given, for his blood sugar had fallen to only .06 per cent and we feared a hypoglycemia. Due to the low amount of carbohydrates in the diet, however, it was decided best to increase the carbohydrates rather than decrease the iletin, and accordingly the next day he was given 44 grams of carbohydrates, 42 grams of protein and 153 grams of fat. He now excreted only 5 to 8 grams of carbohydrates daily, and his blood sugar three hours after the iletin injection was .12 per cent. Later his caloric intake was increased, and he was discharged on carbohydrates 65 grams, protein 60 grams, and fats 215 grams, a total of 2,475 calories. He was taking 10 units of iletin a day when he left the hospital. This is an example where a possible hypoglycemia reaction might have occurred if the blood sugar had not been watched, and this also illustrates the principle of recuperative pancreatic power under proper treatment.

The first two cases illustrate the usual treatment and supervision given a mild case and a moderately severe one without marked acidosis. There are various other cases that would show interesting observations but in order to cover the field allotted to this paper, we will next turn to diabetes with severe acidosis or coma.

Case (No., N. W.) is a very good example of what can be done under energetic treatment and constant supervision with iletin therapy without the use of sodium bicarbonate. A man aged 36, height 5 feet 8 inches, weight 145 pounds, had lost weight for the past three years. Six weeks before admission he developed symptoms of diabetes and refused treatment against the advice of his physician. Two days before entrance to the hospital he became very drowsy, and on admission was in deep coma from which he could not be aroused. Involuntary urination and defecations occurred while he was being examined, and physical examination was negative except for marked emaciation, dehydration, acetone odor to breath, respiration of sixteen to the minute, but very deep and labored. Urine showed a large trace of sugar in the catheterized specimen, and the diacetic test was markedly positive. The blood sugar was .53 per cent and the carbon dioxide combining power was 6.9 mm. of mercury. The patient was placed in bed and warmed under blankets with hot water bottles. He was catheterized and later given a soapsuds enema. Stomach lavage recovered very little, and 400 c.c. of orange juice was given by tube. Hypodermoclysis of 1,000 c.c. of normal saline followed and 400 c.c. of 5 per cent glucose was given intravenously. He was first given twenty units of iletin and four hours later twenty more. Two hours later he was given 10 units more and the patient was allowed to rest during the night. On the second day his general condition was about the same. One hundred and thirty grams of glucose was given in various forms during the day, followed with 50 units of iletin in divided doses every four hours. The next day his blood sugar was .43 per cent and the carbon dioxide combining power of his blood had risen to 17.2 mm. of mercury. On the third day the patient was able to take fluid by mouth, and he received 135 grams of carbohydrates, 10 grams of protein, and 10 grams of fat. He was allowed 40 units of iletin. His blood sugar on the fourth day was .40 per cent. The carbon dioxide combining power was 34 mm. of mercury on the fifth day. He was now mentally clear and was allowed 125 grams of carbohydrates, 50 grams of protein, and 15 grams of fat. Gradually the carbohydrate intake was restricted, being replaced by fats until a basal maintenance diet was established. On the twelfth day the carbon dioxide combining power was normal. His recovery was uneventful, and the same treatment as in the preceding cases followed.

This case illustrates the rules to be followed in the treatment of coma. The rules are as follows:

1. Absolute rest in bed under a nurse's supervision.
2. Patient to be kept warm by the use of blankets and hot water bottles.
3. Catheterization of the bladder.
4. Lavage of the stomach and introduction of glucose in the form of orange juice or glucose solution.
5. Cleansing enema of the lower bowel.
6. Administration of fluid through every possible avenue of entrance, namely, hypodermoclysis

of normal saline, and retention enema by bowel. Fluid intake and output should be measured and recorded.

7. Introduction of glucose in some form by mouth, rectum, and intravenous injection.

8. Administration of iletin subcutaneously or at times intravenously in small divided doses every four to six hours. The use of glucose and iletin should be controlled by the laboratory results on the blood and urine.

9. Treatment of cardiac complications, if they arise, by the use of some form of digitalis subcutaneously.

Sodium bicarbonate is still used by some investigators, but we have not followed it at the University Hospital. We have not found it necessary as a rule, and in the end its results are very transitory unless large amounts are used. We must also remember that after using soda our laboratory results are not a true index of the amount of acidosis which may be present.

In closing permit me to review briefly a few general rules. Our work is not finished when the acidosis and glycosuria is under control. It then falls on the physician to train the patient to care for himself after he leaves the hospital. The old routine established by Joslin is now generally used over the country. The patient must be taught to compute diets and to know the amount of carbohydrates, proteins, and fats allowed in the diet, and how to compute the caloric intake. The urine must be tested daily before the iletin injection, using Benedict's qualitative test as a rule. A quantitative test should be made frequently in order to check results. The patient must be taught to take his iletin under sterile precautions. The symptoms of

hypoglycemia must be known and the necessary treatment for this condition by the use of glucose in some form, as orange juice, milk, lump sugar, or candy. The patient must know the diet to be used in case iletin is discontinued for some reason, and the care for infectious complications that may arise under iletin therapy. In the end the results of patients after leaving the hospital are indices of not only his own intelligence but of the physician's persistence and untiring effort to teach the patient all the possible knowledge he has acquired.

There are men and classes of men that stand above the common herd, the soldier, the sailor, and the shepherd, not infrequently; the artist rarely; rarer still the clergyman; the physician almost as a rule. He is the flower of our civilization; and when that stage of man is done with and remembered only to be marveled at in history, he will be thought to have shared as little as any in the de-

fects of the period and most notably exhibited the virtues of the race. Generosity, he has, such as is possible to those who practice an art, never to those who drive a trade; discretion, tested by a hundred secrets; tact tried in a thousand embarrassments, and what are more important, Herculean cheerfulness and courage.

—ROBERT LOUIS STEVENSON.

INDICATIONS FOR THE USE OF INSULIN*

E. L. TUOHY, M.D.,
The Duluth Clinic
Duluth, Minn.

It is evident that the program committee had a definite purpose in mind in assigning the subjects for this symposium on insulin: it was to bring before you a practical consideration of the changes it has brought about in a consideration of the pathology back of diabetes and the extensions it has provided in the way of treatment.

The first paper has already given you a clear statement of the modern dietary treatment. The third paper will discuss the gravest danger arising from the improper use of this new and powerful therapeutic agent. The final paper, discussing the emergencies arising in diabetes, will cover the very vital subject of acidosis and diabetic coma.

It will, therefore, be the writer's intention not to trespass upon these fields, but devote some time to an analysis of the classes of individuals ordinarily diagnosed diabetic; to point out particularly those in which insulin is a decisive and vital aid in treatment. Finally, to bring out enough of the scientific interest involved in an understanding of some general principles in physiology and metabolism, as to enable us to understand the great volume of current literature that is now giving us such effective directions and rules for its exhibition.

THE PROPORTION OF DIABETICS NEEDING INSULIN

Seventy-five per cent of diabetics properly diagnosed do not need insulin routinely.

1. Of this group the largest number comprise the atherosclerotic or "aging" group—either senile or presenile—and accordingly, range in age from fifty to seventy years. It must be definitely stated, however, that while this group can, as a rule, be properly safeguarded as far as carbohydrate metabolism is concerned by conservative dietary measures, they may at any time come into condition where insulin is a very great aid. We need only briefly mention here the well known states dependent upon acute infection,¹ furunculosis, necessary surgical operations, persistent dermatitis or vulvitis, and a great many other troublesome disorders vitally interfering with sleep and digestion, not to say peaceful, happy life.

This group clearly borders upon the infectious pancreatitis group, known to be associated with acute and chronic infections of the biliary tract—a very excellent field for surgery. However, after all is accomplished that surgery can do, these patients rarely lose all their glycosuric tendencies and take on the attributes of either the vascular or the obese groups.

It must be fully remembered that as these atherosclerotics continue with their advanced, widely distributed degenerative body processes, they enter gradually upon conditions of decline closely simulating a general acidosis. It will be found that it is too much to expect that the late administration of insulin to these patients will restore much bodily function where the process is already greatly advanced. In other words, it is likely that the degenerative process, as far as the Islands of Langerhans are concerned, is as patchy and incomplete as applied to the pancreas, as it is to other organs, such, for example, as the kidney.

It should be remarked that no single patient in this very large group of so-called diabetics should go without the most careful understanding incident upon a thoroughgoing examination of the *objective evidences* substantiating a diagnosis of arteriosclerosis, or, to use a better word, atherosclerosis. This includes particularly a careful study of the eye-grounds and the peripheral arteries; of course, an estimate of the myocardium and the probable coronary circulation; attention to obscure signs of intermittent claudication; finally, a due consideration of the changes incident to widespread sclerosis of the brain and cord.

2. The next important subdivision in this group concerns the so-called "obese" diabetics. It is quite certain here that insulin need only be considered for intercurrent conditions or complications. We should also recall that the obese patient has available a very considerable depot of fat, and in determining anti-ketogenic and ketogenic relationships the amount of fat fed should be correspondingly less.

3. The variety of indefinite endocrine disturbances, the result of probable polyglandular perversion, in which the pituitary and thyroid glands stand out conspicuously. Pregnancy introduces a complicating and stimulating factor at times important. For the purposes of this discussion little need be said, because the group is small and the classical picture of diabetes is rarely even approached.

*Read in symposium before the Annual Meeting of the Minnesota State Medical Association, St. Paul, October, 1923.

4. We may take the same attitude toward the glycosurias incident to cranial injury or cerebral neoplasms, except that the relationship between brain injury and the development of the true picture of diabetes is still much discussed and probably does exist.

5. Finally, renal diabetes must be considered only to point out that it has no connection with pancreatic failure, and therefore does not concern the use of insulin. A word of caution is necessary, however, not to overdiagnose this interesting but rare condition. Unless the fullest of safeguards are put about the diagnosis it is apt to include other conditions, notably the early atherosclerotic type.

THE SEVERER GRADES OF DIABETES

The remaining 25 per cent of severer grades of diabetes have much to hope for from the use of insulin. This concerns the very vital juvenile and early diabetics. It includes any diabetic who is to be operated upon; naturally, any diabetic with an infectious or acidotic complication, and possibly also any diabetic headed toward severe trophic disorder like gangrene or cataract.

First of all, the investigations and studies incident to the isolation of insulin and a development of its properties, establish convincingly the contention, long conjectured, that the disease is due to a failure of function on the part of the Islands of Langerhans.

It can be safely predicted that its use will become more and more extended to those chronic cases, even of milder severity, because the simple fact back of its use, which justifies the greatest hope from its use, lies in the principle of resting overworked, underproducing Langerhans Islands. That was the basis back of our previous treatment for diabetes that was any good. Insulin treatment has not displaced dietary regime; it has simply elevated the dietary treatment to a fixed position, and without it *insulin cannot be used*.

HISTORICAL CONSIDERATIONS

Previous to Allen's regime of food restriction, the old treatment of diabetes, which would simply direct the patient to cut down on the intake of sugars and starches, was absolutely hopeless:

1. It did not consider at all the basal maintenance needs of the body nor much concern itself with the body activities of the patient.

2. Protein was fed indiscriminately, without any particular idea as to the basal needs (two-thirds gram for each kilogram of body weight). Not

only was the intake of protein apt to greatly tax the body, but it did not consider the fact that 58 per cent of this foodstuff was available to the patient in the form of glucose.

3. In addition, it was not understood or considered that 10 per cent of the fat (glycerol-Wood-yatt) was likewise available as carbohydrate.

Then, with the thoroughly scientific regime as outlined by Joslyn, Allen and others, the diabetic was made quite safe, and the overtaxed pancreas, like the overworked myocardium, under the influence of rest attained a certain degree of better function. But, for many individuals, this meant a life of such restriction of energy output as to make it quite impossible for them to carry on or make a living. With fat yielding 9 calories per gram on combustion, to 4 each for either protein or carbohydrate, it was inevitable to attempt the highest possible utilization of fat in providing not only a maintenance body diet but something to work on. Hence, the so-called "high fat" diet as outlined by Newburgh, Marsh, Woodyatt, Wilder and others. The very evident advantage of the fat if excessive ketogenic factors could be obviated was self-evident. Nevertheless, this apparent difference of opinion among accepted authorities was not a little disconcerting to the ordinary practitioner handling diabetics. Therefore, one of the very greatest benefits accruing to the profession from the discovery of insulin is the clarifying of the atmosphere and making certain things quite clear. For purposes of brevity some of these are being summarized:

1. Diabetes is not a disease due to the inability of the tissues to utilize any kind of carbohydrate.*

2. It is due to a failure of the Islands of Langerhans to discharge into the circulation a hormone, and therefore the pathological disorder back of diabetes does reside in that portion of the pancreas.

3. This hormone does not primarily incite or stimulate directly the burning of carbohydrates (Boothby and Wilder²), but simply changes the structural formula of glucose in such a manner as to activate it and make it available as a source of combustion or glycogenic storage. One definite proof of this is seen in the fact that it does elevate the respiratory quotient.

A unit of iletin as now manufactured by Lilly

*It is astounding to note how rapidly the literature has swung about from that long held hypothesis.

& Co. may be depended upon to prepare for utilization 1.5 to 2.5 grams of carbohydrate.

4. Fat is always burned in the body "in the flame produced by the burning of carbohydrates." This was clearly known before but never in the dynamic or dramatic definiteness that the use of insulin has established.

5. Where the proper relationship between the carbohydrate and the fat is not properly maintained the body carburetor cannot function, and the accumulated soot of improper consumption is made up of the ketone bodies—acetone, diacetic acid and beta oxybutyric acid—and an acidosis results.

6. The Toronto committee³ advised that it is fair to assume that carbohydrates, properly available, will burn fat in the proportion of one to two. Recently, Ladd and Palmer⁴ claim that an entirely safe ketogenic relationship ensues both in the normal as well as the diabetic individual where the ratio of one to four is maintained.

7. If one understands reasonably well the ordinary dietetic treatment of diabetes, an understanding of these simple principles will render the use of insulin comparatively easy. It will require no more accuracy than that needed in the digitalization of a case of chronic myocarditis with auricular fibrillation. The present situation is an excellent time to develop a plea for accuracy and a little general mental concentration.

Von Mering and Minkowski, over thirty years ago, gave the lead that unerringly developed this triumphal product of research genius.

We are witnessing this triumph in the isolation of insulin, the result of care and accuracy in the use of *an old method* of alcoholic extraction of the active principle from the glands of internal secretion. We should be willing to meet this by an accuracy of our own. Certainly no hesitating public, as met Jenner with his eliminator of smallpox, awaits us; on the contrary, hordes bare the arm for almost any kind of injection (Loeffler's intravenous included).

The dosages of antitoxins, serums and vaccines, have been as grotesquely indefinite as the dosage of whisky. Likewise, endocrine tablets and their multi-varied combinations have been about as direct as if, in their use, a hunter threw his ammunition at his quarry—he might better remain in his caveman realm and hurl a sharp stone instead.

No method of the oral administration of insulin has so far been accepted, yet drug houses send their

salesmen back and forth across the entire country lustily discussing how their particular company, by superior judgment and skill, is able to extract the pancreatic hormone and combine it variously, stressing their arguments for its supposed benefit by the flimsiest of clinical reports. Why, gentlemen, do we tolerate this sort of thing at the very time when we have before us the dignified attitude of Banting and Best and their co-workers, together with the very ethical and helpful attitude of the American manufacturer of iletin?

It is a most wholesome mental pursuit for all of us to review the present literature on insulin. It helps to remove the cobwebs and dust from our understanding of certain simple physiological processes, and gives us a great variety of surprises and pleasures secondarily.

Just to illustrate one of the many: Crile has long pounded in the idea that a proper glycogenic storage in the liver is a great safeguard for the operative patient. He has elevated the much despised and contumeliously regarded organ to that position where it stands as the great stabilizer even of the nervous system. Now, observe in the literature on the use of insulin just prior to operation, that it is advised that the customary intake of glucose is probably not necessary because the shock incident to the operation will let free sufficient adrenalin to mobilize plenty of the glycogen in the liver to balance combustion properly! This is only a passing instance, of which there are many.

Finally, every patient using insulin in more than temporary periods must come to know the rationale of its use. Hence, the wonderful lead of Joslyn must be followed up. The physician must teach, and if he is to teach he must know. Classes in association with hospitals or clinics are unquestionably most potent factors, and the grouping of these patients has many advantages. Ultimately, a lot of diabetes must be prevented by instruction that will induce those with congenitally weak pancreases to watch their step, dietetically speaking.

THE GENERAL ADOPTION OF THE METHOD OF INSULIN TREATMENT

The new departure in the matter of giving to the profession the results of this most valuable piece of research has been given much and very favorable consideration. Thanks to the liberal attitude of the American manufacturer, the product known as iletin has been available to research and teaching institutions just as soon as its supply was sufficient.

In fact, few medical centers have been without it where its use in emergencies demanded it. As a result, convincing and authoritative reports and discussions have come into the literature freely, and are now available, and in this productive field, we in Minnesota may take full pride in the fine series of articles that have come from the metabolism wards and laboratories of the Mayo Clinic.

It is obviously impossible for you to listen to a discussion such as this and carry away much more than an incentive to ferret out the details. I urge those of you who are interested to go directly to the numerous splendid articles now in the journals⁵ or in pamphlet form. Read as an introduction the special article by the Toronto committee³ in the *Journal of the American Medical Association*. Read the Mayo Clinic⁶ number of the *Medical Clinics of North America* for July, 1923. Study carefully Wilder's nomographic chart, especially as modified by his associate Adams. The September journal of this association—MINNESOTA MEDICINE—in an article by Wilder,⁷ again puts in very usable form an immediate diet for those threatened with diabetic acidosis.

Gentlemen, insulin is ready for us; let us make ourselves ready to properly dispense it. The future will probably greatly expand the field for its usage. It is not impossible that it may include in some

measure metabolic complications such as non-diabetic acidosis. Our private and hospital laboratories should, of course, be equipped to handle the ordinary routine laboratory tests necessary to complement the work of the clinician in these various fields as they are developed.

"PEACE ON EARTH, GOOD WILL TOWARD MEN"

As this is the celebration of the birth of The Great Physician, it behooves each and every one of us to examine the trend of our own life and square it up with the life of him who, through the whole course of his service to mankind, never once faltered in his duty to humanity, and finally gave his life blood that we might see more clearly what true service means.

In our mad rush for financial independence, do we not often forget the nobility of our profession, and have we not ourselves been partly responsible for the lack of respect and the lack of confidence which the public in general has shown toward the medical profession during the past fifteen years? Medicine is one of the oldest of the professions, and the medical man should be the leader in every community to which he administers the healing art. Let us rise up, then, in our might and be the true leaders in our respective communities on all questions pertaining to health and sanitation. Why should laymen usurp our prerogative of leadership in the one subject in which we are experts?

A labor union is all right in its place and has done a great work in bettering the workmen's condition, but, can any one imagine the staff of Cook County Hospital or the Dunning Institution going out on strike for any reason

whatsoever, and allowing the poor human beings under their professional care to suffer and die because of a few paltry dollars? Never! Or can you imagine our city or state health officers leaving their posts of duty while an epidemic was raging? It never has been heard of and never will. It is, therefore, one of the distinguishing differences between our profession and a so-called union.

We may play with politics for a time and accomplish some of the things which are necessary for our economic welfare if we happen to be on the winning side, but the past ten or twelve years have proved to the medical profession of Cook County, at least, that politicians will promise anything before election and shut the door in our faces thereafter.

No, sir, we can never become a labor union, or a political party, nor can we become affiliated with them, in fact, and the sooner the medical profession realize this, the sooner they will become the real leaders in all questions pertaining to health and sanitation, and the sooner we will be given the honor and respect that was once ours without question.

As the New Year opens, let us be governed by the example of the Great Teacher and Physician when he said:

"Inasmuch as ye have done it unto one of the least of these, ye have done it unto me."—*Bulletin of Chicago Medical Society*.

HYPOGLYCEMIA*

J. B. COLLIP, M.A., Ph.D.,

From the Department of Biochemistry
University of Alberta*Edmonton, Can.*

The observation that a condition of hypoglycemia can be produced in a normal animal (rabbit) by the subcutaneous administration of an extract of pancreas containing the active principle was first made by the writer in December, 1921, shortly after he became a co-worker of Banting, Best and MacLeod. It was due more to this observation than to any other single factor that the writer was enabled in a few weeks' time to isolate the active principle of the pancreas in a sufficiently pure and stable form to allow of continuous administration of the same to the human subject. The rabbit test also served as a means of assay of the first insulin used in the treatment of human diabetic subjects. The unit which was first used in this connection was the amount of extract which would produce a 50 per cent decrease in the blood sugar level of a 2 kilogram rabbit. It was later discovered that normal rabbits manifest typical symptoms when the blood sugar has fallen to a level of approximately 0.045 per cent. It was also noted at the same time that animals having such a severe insulin reaction could be recovered within a few minutes by the use of glucose. Adrenalin was also shown to have a beneficial effect on this condition. The physiological unit which was later adopted was the amount of insulin which would produce convulsions in a 2 kilogram rabbit. The clinical unit now in use is approximately one-third of the original physiological unit.

It is very significant that the observations of the effect of insulin on normal rabbits above mentioned which contributed very largely to the successful development of insulin are also essential facts which must be fully appreciated by all who are to use the pancreatic hormone in clinical practice.

There would seem to be no essential difference between the state of profound hypoglycemia which can be produced in a normal animal by adequate insulin dosage and the similar state which is sometimes produced in a diabetic subject by insulin overdosage.

The primary effect of the administration of insulin to either a normal or a diabetic subject is to cause a fall in the level of blood sugar. What the exact nature of this primary effect may be is not yet fully understood. It has been well established that glycogen synthesis takes place in the liver of a diabetic dog under the influence of insulin. It may be possible therefore that sugar storage in the form of glycogen may account entirely for the decrease in blood sugar level of both normal and diabetic animals which have received insulin.

It is a noteworthy fact, however, that the liver of a normal rabbit which has manifested a hypoglycemic reaction following insulin administration may on occasion be found to be practically free of glycogen. Mann¹ has also very definitely shown that the liver is non-essential to the production of the hypoglycemic reaction by insulin. There are factors, therefore, other than glycogenesis which may account for the disappearance of sugar from the blood of insulinated individuals. Best and Hepburn early demonstrated that the respiratory quotient rose in diabetic subjects within a few hours after the injection of insulin, and shortly before this the writer had shown that ketosis could be abolished in depancreated dogs by the use of the pancreatic hormone. These two observations indicate that glucose burns freely in the tissues of insulinated diabetic individuals. It is herein that the chief value of insulin lies. The tissues of the insulinated diabetic subject are enabled to utilize glucose and thereby are capable of burning fatty acids to the normal end products CO_2 and H_2O without the accumulation of ketone bodies. Normal metabolism therefore ensues and acidosis is abolished.

When as a result of insulin overdosage, the blood sugar has fallen to a very low level, an unphysiological state is produced and a typical train of symptoms ensues. Almost immediate recovery from the hypoglycemic symptoms can be effected if the level of blood sugar is suddenly raised as by the administration of glucose. It is of interest in this connection to note that there is a certain amount of evidence that a spontaneous effort is made to raise the blood sugar level in the hypoglycemic state through the discharge of adrenalin from the supra-renal glands.² On occasion we have noted a pilo-motor effect in rabbits in a condition of hypoglycemia. If the dose of insulin administered is just sufficient to produce convulsions in an

*Presented in symposium at the Annual Meeting of the Minnesota State Medical Society, St. Paul, October 11, 1923.

experimental animal, spontaneous recovery may occur. The end result of insulin overdosage is, as a rule, death unless recovery is effected through the administration of glucose. If a condition of profound hypoglycemia is maintained for some hours before glucose is administered, the effect of the latter may not be so striking. Complete recovery may not occur for some time. In other words, the maintenance for any length of time of this unphysiological state of profound hypoglycemia may result in the production of changes which are to a degree irreversible. There is a probable analogy here between the coma of long duration in the diabetic and the coma of profound hypoglycemia.

Theoretically, recuperation of the insular tissue of a diabetic and thereby increase in native tolerance for carbohydrate is most likely to occur if the blood sugar be kept within or even slightly under normal limits by adequate insulin therapy and a proper dietetic regime. In this, the most scientific type of insulin therapy, there is always the constant danger of the hypoglycemic reaction. Practically, therefore, if such a reaction be met with it should be counteracted at once.

The nearest parallel to the hypoglycemic reaction observed following insulin administration is the condition of hypoglycemia described by Mann³ as observed by him on deliverized dogs. Mann has shown that following complete removal of the liver the level of blood sugar falls gradually and progressively, that typical symptoms occur when a certain low level is reached and that temporary recovery is effected by glucose administration. Mann found, however, that these deliverized animals though benefited for some hours by glucose administration ultimately died in spite of the sugar injections. These results demonstrate that the liver plays a very essential part in the regulation of blood sugar level.

The mechanism for the regulation of blood sugar concentration in the normal animal is in all probability a very complex affair. Such factors as the normal functioning of the pituitary, pancreatic and suprarenal glands and liver together with the actual metabolic needs and the concentration of blood sugar itself must all form integral parts of this regulatory mechanism. When in experimental work, therefore, a marked deviation from normal blood sugar standards is noted, it is not always a simple task to determine just what part of the nor-

mal mechanism has been thrown out of gear, so to speak.

As soon as it had been established that the functions of sugar storage and sugar combustion in the animal were dependent upon insulin activity, the writer felt that in all probability further research would disclose the existence of an insulin-like substance in the vegetable kingdom, since plants are sugar burners. It was later shown⁴ that extracts made from a variety of plant sources may produce hypoglycemia when injected into normal rabbits, or a very definite lowering of the blood sugar of depancreatized dogs. It was noted, however, that whereas the administration of insulin is followed by a prompt fall in blood sugar, the fall in blood sugar which occurred following the administration of plant extracts did not take place till some hours or, in certain instances, some days following the administration of the extract. The effect of injected plant extracts was therefore quite distinct from the effect of insulin.

It was later observed⁵ when a condition of profound hypoglycemia had developed in a normal rabbit following the administration of a plant extract, that the injection of a small amount of blood of such an animal into another normal rabbit produced in the latter animal a condition of hypoglycemia. The hypoglycemic reaction developed in the second animal usually within a day. It was also found that such animals could be temporarily recovered from the hypoglycemic state by the injection of glucose. The condition of profound hypoglycemia continued to recur even after glucose administration and the animals would as a general rule ultimately die. The blood of such animals would, however, produce similar effects when injected into other normal animals. Blood passage of this effect could be carried on successfully to an indefinite extent. When this phenomenon was first observed it was thought that an organism might be the underlying cause. This possibility was excluded, however, when it was shown that such a potent blood was still active after autoclaving.⁶

It has since been shown that a similar result can be obtained with the blood of insulinated rabbits. It is necessary to give a large overdose of insulin and to keep the injected animal in a condition of profound hypoglycemia for many hours. The blood of the insulinated rabbit has then produced

hypoglycemia when injected into other normal rabbits.

Spontaneous hypoglycemia may be noted on occasion in certain individuals in a rabbit colony. The liver in all such cases observed by us has been found to be full of cysts, and coccidia ova have been demonstrated on microscopic examination. The blood of such an animal will likewise produce hypoglycemia when injected into other normal rabbits.

Recently we have been able to show that prolonged starvation of rabbits results in the manifestation of profound hypoglycemia just prior to death. The blood of these animals will also produce hypoglycemia if injected into other normal rabbits.

The subcutaneous injection of certain guanidine compounds may also result in the manifestation of profound hypoglycemia. The blood of guanidized animals under these circumstances has also been observed to produce hypoglycemia when injected into normal rabbits.

I have recently obtained through the kindness of Dr. Mann, of the Mayo Clinic, a sample of blood from one of his deliverized dogs. The injection of this blood into rabbits was followed by the manifestation of hypoglycemia.

The production of the hypoglycemic state by any of the methods above described stands in sharp contrast to the typical insulin reaction. The in-

sulin reaction is manifested within a few hours of the time of the injection whereas the hypoglycemic reaction otherwise produced develops much more slowly. The phenomenon of "delayed action" can also be seen after the administration of pancreatic extracts which have been kept slightly alkaline throughout their preparation.

As hypoglycemia can be produced in such a variety of ways, one is led to ask this question: "Is there some fundamental similarity in the mode of activity of these various agents, insulin included, or is it merely chance parallelism which we are dealing with?"

It is conceivable that liver injury might explain all of these results. Further research only can settle the issue, meanwhile I present the results for what they are worth.

FROM A COMMITTEE REPORT OF SEVENTY-FIVE YEARS AGO

It is in vain to attempt the enforcement of any direct legal restrictions upon the people in regard to medicine; if they choose quacks and quackery, no law which would forbid such choice can stand in this country.

That there should be some laws in relation to the medical profession there is no question. But the ideas which are commonly entertained in regard to the scope and object of these laws are somewhat indefinite even among medical men. In the opinion of the committee, the object of these laws should be simply this—to give protection to those measures which are calculated to secure to the community a well-educated body of physicians. Everything inconsistent with the attainment of this object should be discarded. No class of physicians, professedly and exclusively devoted to any system of opinions and practice, should as such receive such protection. The medical profession should be a single body of men without any prescribed set of opinions. And the ground of admission to their ranks should have no reference to opinions; but there should be the greatest latitude

in this respect. Character and education should furnish the only basis of membership.

We are persuaded that, if the profession as a whole should take this view of the subject, we should stand in a much better position before the public than we now do. We should then be able to propose to the community the question, clean and stripped of all incidental and embarrassing considerations, whether they would sustain an educated or an uneducated profession. We should stand simply and clearly upon our merits in this respect, and should command the respect and confidence of the great majority of the community. But whenever other grounds are taken and opinions are made in any degree the basis of admission or expulsion, we lose this respect and confidence, for we enter into competition with opinionists of every grade, and upon their own level. At this moment, the strife between the regular profession and other self-constituted medical bodies is regarded by even sensible men in the community as being for the most part a war of opinions. And some ground is given them for this view of the subject by occasional acts by individuals, or even by some of our associations.—A. M. A. Bulletin, Nov., 1923.

THE TREATMENT OF THE EMERGENCIES OF DIABETES*

RUSSELL M. WILDER, Ph.D., M.D.

Division of Medicine, Mayo Clinic

Rochester, Minn.

There is little reason to believe that insulin will materially affect the underlying metabolic fault in diabetes. In fact, it is possible, as certain observers maintain, that the better nutrition which the use of insulin permits, may hasten the progress of the underlying disease more than formerly under régimes of undernutrition. Instances of improvement in tolerance following the institution of insulin treatment in the Clinic have been observed and commented on, but the patients either had the chronic type of diabetes, or were in an early stage of the acute and inherently progressive disease. The severest cases have not shown such improvement; a few of our patients are now requiring larger doses than they did a year ago, and one of the children seems to be reaching a stage of complete dependence on insulin. It is highly probable, therefore, that the patients with the acute type of diabetes will, in a few years, lose all their native tolerance and become completely diabetic. I wish to emphasize this probability, first, because of the necessity of envisaging the prospect of having gradually to increase the present daily dose of insulin, and second, because of the importance of insuring an uninterrupted supply of insulin in cases of complete diabetes. When patients have been kept alive by insulin long enough for their native tolerance to evaporate completely, their diabetes will be complete or total, such as has never been encountered in the past, and if, therefore, they are deprived of their quotidian injections, for ever so short a time, acidosis will develop with remarkable rapidity, and neither fasting nor careful dieting will avail to protect them. Their metabolism will consist exclusively of the ketogenic acids, regardless of their diet. No glucose will be available, and 100 or more grams of aceto-acetic acid will accumulate daily. A hypothetical example may throw light on the amount of insulin which will ultimately be necessary to keep such patients alive.

From available data on the energy exchange of

normal resting individuals, it may be calculated that a man, thirty years of age, 5 feet 10 inches in height, and weighing 150 pounds, will generate approximately 1,700 calories a day. With no energy derivable from glucose, this heat must all be supplied by ketogenic acids, and the amount of these in terms of fat would total about 180 gm. According to prevailing views, such an amount of fatty acid would necessitate at least 56 gm. of oxidizing glucose, if acidosis is to be avoided. It might be estimated, therefore, assuming that a unit of insulin will accomplish the metabolism of 1.5 gm. of glucose, that 37 units of insulin would be necessary daily. The unit of insulin, however, may not have such potency under these conditions. The method of assaying insulin clinically, which gave the average figure stated, was proposed chiefly as a means of comparing the strength of one lot of insulin with another, and it is obvious that the figure can be obtained only under the condition imposed for the clinical assay.¹ Infections and other complications, as well as nervous influences and probably severe acidosis itself, may be expected to affect it unfavorably, and, in the assay proposed, only those patients were selected for the test who were "free from infections or other complications and comparatively calm in temperament."

It is not unlikely that the hypothetical patient under discussion would require at least 1 unit of insulin for each necessary gram of sugar, and this would make his minimal daily insulin requirement 56 units. Furthermore, these are figures for a person at rest. If the hypothetical patient is to carry on a gainful occupation, and is to be given sufficient food to supply the energy for such work, the requirement will be still greater. Thus, we have found it desirable, in order to plan satisfactory large diets that are palatable, to establish a tolerance for at least 100 gm. of glucose, which might necessitate the injection of 100 units daily.*

As a matter of fact, one of our patients, D. D. (Case A386254), a child now three years old, has recently required 60 units of insulin daily with a food allowance of carbohydrate 50, protein 50, fat 100. As was reported previously, this same child developed severe insulin shock a year ago with only 12 units. There may be undiscovered infection complicating the case at present, but a

*Read in symposium before the Minnesota State Medical Association meeting, St. Paul, October 10-12, 1923.

*All references to insulin dosage in this paper are based on the original "Iletin" unit of the Eli Lilly Company, namely their "H-20" material.

great decline in tolerance seems to have occurred during the year. The insulin dosage has been raised gradually. With 60 units of insulin a day the child is apparently normal. With a smaller dose he develops acidosis at once.

To most of the patients treated thus far, it has been possible to give insulin in a single dose daily, or in two doses; this is naturally preferable to more frequent injections. However, it is probable that, as the patient advances toward a state of complete diabetes, it will be necessary to increase the frequency of insulin injections in order to shorten the interval between doses. The child, D. D., is receiving 60 units in three doses, 25 units before breakfast, 20 at 2 P. M., and 15 at 8 P. M. We have now used insulin in the treatment of 370 patients, of whom 181 are continuing its use in their homes. These patients have received a fair training in dietetics, and have been advised with regard to the necessary dose of insulin. They are weighing their diets and taking regularly from 15 to 45 or more units of insulin daily. The greater number of these patients are strong, and able to engage in their normal work. Disaster, however, has overtaken a few of them, and I anticipate that as the others more closely approach the state of total diabetes, disaster will become more common. A few patients have failed to receive their allotments of insulin. For the most part, they have been supplied through their home physician, the material being mailed to the physician by the manufacturers. Occasional slips have occurred through loss or damage of the material in the mail. All of the patients have been carefully instructed, both while they were in the hospital and subsequently by correspondence, to insure themselves against such accidents by always keeping on hand at least one extra month's supply of insulin. In spite of such warnings, patients occasionally find themselves without insulin. In one case death in diabetic coma resulted within thirty-six hours after the injections were discontinued, and at least three patients have returned for treatment just in time to avoid a similar catastrophe.

The danger to the patient with complete or nearly complete diabetes from missing an injection imposes the enormous responsibility on everyone concerned with the use of insulin, of seeing that patients receive their injections of an insulin of satisfactory potency regularly and without fail. I

feel sure that the members of the Eli Lilly Company fully appreciate their responsibility, and are making every effort to maintain the product at a standard strength. I regret that I have less confidence in the patient's physician and in the patient. Certain patients will forget about their reserve of insulin, others will be persuaded to try some of the many other pancreatic preparations on the market, with results that must inevitably prove tragic.

Acidosis and coma, if the patient is conscientious and well-trained, are almost always invoked by some complicating infection or infectious disease. Anesthetics and surgical procedures do, it is true, precipitate acidosis and confront us with a similar problem. A careless, ignorant, or willful patient may, through dietary indiscretion, promptly develop diabetic coma, but the fate of such a patient is less disastrous than that of the conscientious and intelligent patient who is suddenly stricken with pneumonia, typhoid fever or measles. It is to the management of such infectious complications that I wish especially to call attention.

THE MANAGEMENT OF INFECTIOUS COMPLICATIONS

The influence of the infections on the metabolism of the diabetic patient is a subject deserving further study. An immediate break in tolerance is produced which usually results promptly in acidosis, and unless suitable measures are instituted to combat the accumulation of acetone bodies, the outcome is almost certain to be coma and death.

Whatever the mechanism involved, the facts are that a patient with partial diabetes may be suddenly converted by infectious processes into one with total diabetes, and during the continuance of the infection, doses of insulin as large as, or larger than those computed for patients with total diabetes may become necessary immediately and continue necessary until the complicating infection subsides. It has been difficult sufficiently to impress patients and physicians with the necessity for heroic use of insulin in such emergencies. So much has been written concerning the danger of the insulin reaction, or insulin shock, as we prefer to call it, and of the necessity of balancing the insulin dose with the food, that a certain timidity has been engendered. For example, a patient who is doing well on a certain dose of insulin and a definite, properly calculated and weighed diet develops an infectious complication. His appetite fails, and he

or his physician thinks that, since he cannot eat, the dose of insulin should be reduced. Metabolism, however, does not stop by reducing the diet; it may, in fact, be increased by the fever, and the insulin, even in the absence of food, may have a much feebler action than usual, as the result of the deadening effect on it of bacterial toxins. The consequence of reducing insulin dosage under such circumstances is the rapid development of acidosis, and the precipitation of coma. One child was rushed back to the Clinic in coma as the result of such a mistake.

It cannot be too strongly emphasized that the advent of an infection always demands not less, but more insulin, and that large doses of from 15 to 25 units, may be needed every six hours, so long as the infection continues. As in the case of uncomplicated but total diabetes, the interval between doses must be brief, and the daily dose must be divided and administered in three or four equally spaced injections.

It is important to use carbohydrate fairly liberally. Fruit juices are well tolerated, and contain sugar in an especially available form, in large part as fructose. It is considered that orange juice contains ten parts of carbohydrate. We make it a rule to administer by mouth 100 gm. of orange juice with every 20 units of insulin injected, and have found that in toxic cases this amount of carbohydrate will satisfactorily buffer the insulin and at the same time supply the sugar necessary to counteract ketosis. Besides the carbohydrate of the orange juice, such soft foods as the patient will accept, especially milk, cream and eggs, are given. However, the total carbohydrate ingestion should not exceed 100 gm. daily. It does not seem necessary or desirable completely to avoid glycosuria at such times; the control of acidosis is primary. Every effort is made to prevent the accumulation of acetone bodies.

Despite fairly large doses of insulin and adequate carbohydrate, an exacerbation of the infectious process may at any time provoke sudden acidosis. It is, of course, extremely helpful to have at hand the laboratory facilities for examining the blood for the carbon dioxide capacity of the plasma, but in the absence of such facilities, the respiration of the patient is a reliable indication of the state of the alkali reserves. Air hunger, the long deep "Kussmaul" type of respiration, is a sure sign that

the stores of alkali are depleted, and such breathing, if accompanied by a strong acetone smell and other definite clinical evidence of acidosis, is an indication for giving soda. The disrepute into which sodium bicarbonate has fallen is undeserved. An intravenous injection of 500 c.c. of a 6 per cent sodium bicarbonate solution will immediately affect a critical acidosis, and to neglect its use in such an emergency is unjustified. Insulin and carbohydrate may accomplish the same result as soda, but the delay entailed may tip the balance unfavorably. Severe diabetic acidosis is dangerous, and should be controlled as rapidly as possible.

When the infection subsides, the patient's native tolerance, which has been temporarily suppressed, returns in part at least, and the necessity for large insulin doses passes. It is then important to reduce these doses in order to avoid overaction and insulin shock. It is usually possible to return gradually to the diet and dosage which were effective before the onset of the complication.

It has been necessary to combat a number of very severe infections in the large number of diabetic patients observed in our wards during the year, and by carrying out the general principles discussed, the mortality has been kept very low.

SUMMARY

Use enough insulin to control acidosis. This may require from 60 to 100 units daily, and should be given in equally divided doses at six-hour intervals.

Administer by mouth 100 gm. orange juice with every 20 units of insulin injected.

Watch the breath for the odor of acetone; examine every voiding of urine for diacetic acid. If possible, and if doubt exists, obtain the carbon-dioxide capacity of the plasma. If signs of severe acidosis develop, the Kussmaul type of respiration or a carbon-dioxide plasma capacity below 20 volumes per cent, use sodium bicarbonate as a 6 per cent solution intravenously, giving 500 c.c., and repeating this injection if necessary.

Reduce the dose of insulin and readjust the diet when the complication has passed.

THE EAR IN GENERAL MEDICAL DIAGNOSIS*

HAROLD I. LILLIE, M.D.

Section on Otolaryngology and Rhinology, Mayo Clinic,
Rochester, Minnesota

In the practice of medicine at the present time very complex problems in diagnosis are dealt with. Such a state of affairs has naturally led physicians to a more intensive study of conditions affecting certain organs, or groups of organs. The fact is sometimes lost sight of that symptoms referable to certain regions may be due to disease conditions in a distant part, or at least a part quite removed from the site of the original complaint. Recognition of this phenomenon is the function of the diagnostician. The otologist is expected by the state boards of medical examiners to be able satisfactorily to examine the chest, abdomen, and central nervous system, to interpret laboratory findings, and so forth; in other words, to have at least a good general understanding of the general physiology of the body. The tendency is quite prevalent, among general diagnosticians, to relegate to the otologist all patients with symptoms referable to the mechanism of the ear, although in the successful management of many such cases the services of the internist are indispensable. A better general understanding of the symptoms related to the ear referable to certain deranged conditions of other parts of the body would be of great advantage to many internists. Examination of the eye is resorted to for confirmatory evidence by many internists in certain types of cases. It must be borne in mind that each organ forms an integral part of the complex whole.

Physicians, on final analysis, are more or less familiar with many of the causative factors of symptoms related to the ear, but forget that they know about them. I shall mention here some of the more common general conditions which may affect the mechanism of the ear for the sole purpose of recalling them to memory. The symptoms which may attract the patient's attention to this mechanism may be classified in three main groups: tinnitus aurium, deafness, and pain. Vertigo and its sequelae, nausea and vomiting, are not generally regarded as symptoms due to disorders of the ear.

TINNITUS AURIUM

The actual causal factor of tinnitus, even the histologic and pathologic factor, is very difficult to determine. Tinnitus may be caused by local conditions within the mechanism of the ear, but very often it is caused by quite remote conditions. When one recalls that the arteries supplying the ear are end arteries as demonstrated by Shambaugh, and that the internal carotid and internal jugular vein are separated by only a thin plate of bone, one can easily understand how changes in the nervous mechanism controlling the caliber of the blood vessels might readily have a very definite effect. It may be said in general, I believe, that tinnitus is caused by some disturbance of the local circulation. It is also true that there is a more or less constant tinnitus in normal persons, but this is disregarded. Anyone, when tired, may sit quietly, and by merely listening will notice tinnitus.

One would expect that, in cardiovascular disease, tinnitus might be a common symptom, and this is the clinical experience of most otologists. Obviously, the treatment is not local. Occasionally the patient is terribly distressed, and not infrequently has a suicidal tendency. The patient's particular fear is that the tinnitus may be a precursor of oncoming deafness, but this does not necessarily follow.

Tinnitus in some form is usually associated with arteriosclerosis of the central nervous system type, and may be very severe. Patients with high blood pressure, originating in organic disease in contradistinction to the essential hypertension type, may manifest tinnitus as one of the early symptoms. In cases of the blood dyscrasias, the leukemias, polyemia, anemias and polycythemia, tinnitus and deafness are associated symptoms because of the plugging and congestion of the small end vessels. Occasionally, in valvular diseases of the heart, the bruit may be heard by the examiner. I have examined three such cases. Pelvic and abdominal disorders, as described by Woakes, are a well recognized cause of tinnitus. In early stages of pregnancy tinnitus may be a prominent symptom. Tinnitus has also been observed repeatedly at the Clinic in both pre-operative and postoperative abdominal cases. In fact, two very definite instances of patients complaining of tinnitus were found, on general examination, to have uterine fibromas, and their removal relieved the tinnitus. Postoperative tinnitus is a rather difficult symptom for the general

*Read before the Minnesota State Medical Association, St. Paul, October 10-12, 1923.

surgeon to explain unless it is recalled that the nerves controlling the caliber of the vertebral arteries, and also the basilar artery and its branches, including the internal auditory, which supplies the labyrinth, come from the inferior cervical ganglion. The stomach and other abdominal viscera are largely supplied by the pneumogastric nerves, and the communication between the vagus and the inferior cervical ganglion is established by means of a fasciculus from the vagus to the inferior cervical ganglion.

Because of the injurious effect on the mechanism of the ear, constipation and gastro-intestinal stasis are more important factors than is generally recognized. A fair majority of deaf persons, particularly women, are constipated and often obstipated. The effect may be vascular and toxic. There are many other less common toxic factors. Focal infection may play its part in the same way. The effect that quinin, salicylic acid, and other drugs may have on the ear is well recognized.

Disturbances of metabolism, myxedema and its allied conditions, often present symptoms referable to the ear. The effect probably is secondary to the changes in the blood vessels and perhaps in the concomitant tissue changes. In a study of the mechanism of the ear in cases of myxedema, it was found that both the cochlear and vestibular branches of the eighth nerve might be involved. The function was usually below normal, in certain cases considerably below. It has been apparent that the state of health is an important factor in the condition of this special sense nerve.

Neurasthenia and allied disorders are the most common general and functional conditions which may have concomitant symptoms related to the ear, and it is in such cases that the otologist has the most difficulty in satisfactorily explaining symptoms to patients. Local treatment per se will not relieve the symptoms. In the syndrome of an acoustic neuroma, Cushing has shown that tinnitus is the prodromal symptom. Tinnitus, deafness, and vertigo may be the early symptoms of many complex cases of intracranial tumor, and special examination of the mechanism of the ear may yield information which will aid materially in the localization of the lesion.

Pain.—Pain in any part of the body will induce a patient to seek relief more often than any other symptom. Pain in the ear and mastoid, which is

not caused by inflammatory diseases, is encountered in daily practice. Because of the complexity of the nerve supply of the mechanism of the ear, there are many possible causal factors; among the more common are the otalgia and mastoidalgia due to unerupted third molar teeth, dental caries, and lesions in the pharynx and nasopharynx, as shown by New. Occasionally, glossopharyngeal neuralgia or neuralgia of the sphenopalatine ganglion is a factor; obviously, the treatment is not local. However, patients with nasopharyngeal tumor have been observed, who have had repeated incisions of the drum, and mastoid operations. Young adults have been seen in whom mastoid operation had been performed or advised because of otalgia, whereas the pain was really caused by an unerupted third molar, or a sphenopalatine ganglion syndrome.

Occasionally a patient complains of pain in the ear coming on early in the morning, which is relieved by arising and moving around. This occurs most commonly in patients past middle life. In large measure it may be overcome by using several pillows to sleep on. Recently I had a patient with this syndrome who is an eminent otologist, and he had suspected some trouble with the posterior sinuses. Pain in the ear, following exposure to wind, may be avoided by placing cotton in the canal.

Vertigo.—A most troublesome group of patients to deal with, from the standpoint of both otologist and internist, are patients with incapacitating vertigo, not infrequently accompanied by nausea and vomiting. This chain of symptoms is recognized as the Menière syndrome, which is the result of toxic neuritis of the eighth nerve. Any source of focal infection, all dietary toxic factors, the excessive use of tobacco, moonshine, and so forth, must be eliminated. There is great difficulty in the satisfactory management of this group of cases. Occasional attacks do not cease until the nerve is totally destroyed.

THE PROBLEM OF THE DEAFENED

The totally deaf person assumes that nothing can be done for him, but the person only partially deafened is constantly grasping for anything or any treatment that he hopes might restore his hearing, and often he is preyed upon. The problem of the deafened is not only the problem of the otologist, but the problem of the physician, friends, and

the clergy. Ordinarily, little may be accomplished with regard to restoration of the hearing in a large majority of the afflicted, but occasionally, in early cases of deafness due to disease of the nerve, rather striking results have been attained.

The mental attitude of the deafened person is paradoxical: he is generally morose and melancholy, and tends to isolate himself, which is in contrast to the blind person, who is happy, bright, and cheerful. I would prefer deafness. Edison says that he enjoys deafness because he can concentrate better. Physicians must show deafened people that the outlook is better than they expect. Hardly anyone objects to the use of corrective lenses for their vision, and the objection to the use of artificial hearing apparatus must be overcome. Employers must be shown that in certain lines the deafened make more suitable employees than individuals whose hearing is normal. In this state, a league for the "hard of hearing" is being formed, which deserves the moral support of the public. The science of lip reading is being developed to a remarkable degree, and I believe that in it lies the salvation of the deaf.

SUPPURATIVE DISEASES

All are familiar with the suppurative diseases, but I wish to call to your attention the fact that patients with infected sinus thrombosis have been treated for typhoid fever and bronchopneumonia, and that brain abscess has been overlooked as a complication from infected conditions of the ear.

SUMMARY

Symptoms referable to the mechanism of the ear may be grouped under three main heads: tinnitus aurium, deafness, and pain. Vertigo, with its sequelae, nausea and vomiting, is not generally thought of by the laity as symptoms referable to the ear. Many conditions other than those local to the mechanism of the ear may cause these symptoms. It is within the province of internists to recognize the causal factors. The problem of the deaf does not rest with the otologist alone.

DISCUSSION

DR. HORACE NEWHART, Minneapolis: I wish especially to thank Dr. Lillie for his excellent paper, for in it he has eloquently emphasized the point which I have been trying to put over for the past ten years in a feeble attempt to instruct our undergraduates at the University of Minnesota in otology. That point is simply this: The ear must not be looked upon as a disassociated organ taken apart from the rest of the body. This of course has been brought out in connection with the labyrinth, but I think we should also call special attention to the large number of cases of nerve deafness which we encounter, those in which the lesion is not so much in the middle ear but is found in the sound perceiving apparatus, the cochlear apparatus. These cases who come to us without any evidence of inflammatory disturbance in the middle ear but are hard of hearing, should be considered quite as much from the point of view of the internist as of the otologist. Therefore in such cases we should seek the cause in other parts of the body.

Dr. Lillie has called attention to the gastrointestinal tract. To illustrate the point let me say that recently we have had occasion to check up on a patient who had been the rounds of the different otologists for several years, had gone through all the classical operations of tonsillectomy, which perhaps was needed—undoubtedly was in this case—and straightening of the nasal septum. Yet the tinnitus persisted and the impairment increased. She was referred to the internist because we could do nothing to ameliorate her condition, and fell into the hands, through the internist, of the surgeon, who removed the gallbladder. The results in this particular case are so striking as regards the improvement in this patient's hearing, and diminution of the symptoms, that I feel I must call your attention to the possibility of gallbladder disease being a casual factor in nerve deafness, and suggest the gastrointestinal tract as a line of more thorough investigation.

To illustrate still further the suggestiveness coming from ear symptoms: A patient not over two years ago was referred to us by the internist because of the marked symptoms suggesting disturbance of the static labyrinth. The patient was extremely nauseated on arising in the morning, oftentimes could not retain food after she had gotten up, and was in an uncomfortable condition a good part of the year. Examination showed an extremely irritable labyrinth and nothing more. The hearing function was normal. Inspection of the middle ear showed nothing pathological. Yet on attempting to turn this patient in the turning chair, the reaction was so severe that it was almost impossible to carry out the procedure. She was referred back to the internist, who made a careful gastrointestinal examination, finding absolutely no free hydrochloric acid. The patient was cured of her vertigo and nausea in one week by putting her on the right track as regards the digestive tract.

IRRITATIO CONJUNCTIVAE

EDUARD BOECKMANN

St. Paul

With the eyes open, the greater part of the cornea and the bordering lateral sectors of the bulbar conjunctiva are, between the winkings, exposed to the air. The air is never pure but in mid-ocean, in the high mountains, in the arctics and partly in the woods. Our eyes are ingeniously, richly and beautifully supplied with both defensive and offensive armaments for protection against irritations and infections from the air. There is already some protection in the supercilia, but more so in the cilia themselves; there is protection in the sensibility of the skin, but vastly more so in the sensibility of the cornea, which is the most sensitive organ in the human body. On this sensibility depends the frequency of the winkings and the squintings of the lids, and on this sensibility depends the constant secretion of tears with their antiseptic virtues. The conjunctiva and cornea are furthermore protected by a delicate mucous film from the tubular glands in the conjunctiva and perhaps from the epithelium itself and there is a good supply of adenoid tissue particularly in the retrotarsal folds for direct action upon the prospective invader. Besides, the conjunctiva is richly supplied with blood vessels and with lymphatics with the preauricular glands for their rendezvous.

Thus the eye is by nature well prepared to meet the air and defend itself against the hostile elements it contains, and *legio* are the people who pass their span of life with little or no inconvenience, but another *legio* does not fare so well.

The air both inside and outside our dwellings is more or less saturated with ordinarily invisible impurities of all kinds. All of us can see them with the naked eye, when sunlight strikes a darkened room through an opening,—myriads of now visible particles, mineral, vegetal and animal (Pasteur); all of them more or less irritating to the eye; many of them infectious.

Pure air is an everlasting friend; impure air is an eternal enemy with which we are in constant fight and the open eye has all the time its share. No wonder that it will be rather difficult to find a perfectly normal, pale, smooth, thin and transparent conjunctiva, while the cornea, which is not a hiding place for "dust" and which gets the main

benefit from the winkings, remains immaculate but for frequent increase of conjunctival mucus, which moves over it in the shape of a thin veil, visible on close inspection with the winkings of the lids or demonstrable by oblique illumination or transillumination. Regularly the conjunctival sac is inhabited by some bacteria,—as a rule harmless saprophytes, which, however, may give rise to some chemical irritation but no infection. The conjunctiva is not a good breeding place for bacteria, fortunately; still, if we neutralize the winkings by bandaging the eye, making a tearless, quiet incubator of it, the bacteria will multiply considerably, for which reason I am an avowed enemy of tight bandaging except in certain cases. It is impossible for the winking eye to remove all the bacteria or other irritating elements that have invaded and even multiplied during sleep, when the eyes bandage themselves; a fight with nature will result and it is this fight that constitutes the objective picture of *irritatio conjunctivae* and which causes the subjective symptoms by irritation and poisoning of the sensitive nerves.

Irritatio conjunctivae—also called catarrh or eyestrain—is without comparison the most frequent of all diseases of the eye. It is an every-day disease and a disease for every doctor. Hardly anybody escapes it in some form or other. It begins early in life, becomes more and more frequent with age to include almost all old people. Still, most people experience little or no trouble and go through life without calling on the profession. It is particularly those who belong to the farm-laborers and who depend more upon their hands than on their eyes for their daily bread and who only read the newspapers or the hymn book, who don't pay much attention to a little conjunctival irritation. Those who spend hours with books in stuffy, illy lighted rooms, or in rooms with electric or kerosene lamps, which irradiate heat, and those not receiving adequate protection from shields or glasses, or failing to have the source of illumination behind the head,—those are the ones so often troubled from conjunctival irritation. It is particularly the nervous, high strung, hypersensitive people, that will suffer from *irritatio conjunctivae* more than the indolent. Consequently girls will often have more trouble from irritation than boys, and women more than men. But there is no reason to take girls and boys out of the school, simply because they suffer from *irritatio conjunctivae*. The eyes are made to be used and I think it

is a sane and safe advice to let them use their eyes for all they are worth. A night's rest is all the eyes need and idleness is no cure for *irritatio conjunctivae*.

Irritatio conjunctivae may not stop with the conjunctiva; it may invade the subconjunctiva, the caruncula, the semilunar folds, the cilia, the Meibomian glands, and the canaliculi—and often does. Finally it may extend to the episclera, the preauricular glands and the orbital contents. This invasion of the eye is usually bilateral, but often the one eye is invaded to a greater extent than the other.

Although *irritatio conjunctivae* may be the result both of physical, mechanical, chemical and parasitical elements, usually in combination, the bacterial invasion from the air is undoubtedly the most frequent cause. There may be more or less susceptibility in different individuals, but once rooted in the conjunctiva it becomes a more or less chronic condition. It may be and usually is impossible in a given case to prove the nature of the real offenders. I for my own part have more and more come to the conclusion that tuberculous irritation is not uncommon. It is difficult for tubercle bacilli to breed in the conjunctival sac and real tuberculous conjunctivitis is also a rare disease. I am very slow in accepting an endogenous origin of the same. This is, however, a disputed question. It seems to be easier for the tubercle bacilli to penetrate the conjunctiva and be carried to the subconjunctiva, episclera and the preauricular glands through the lymphatics. When I find indolent enlargement of the preauricular glands, I am always suspicious of the irritation being of tuberculous nature, well knowing that other elements can do the same. A close examination for the presence of preauricular glands with the tip of one's index finger should always be done in *irritatio conjunctivae*. If demonstrated at all, it always means they are enlarged, as the normal glands are so small that they escape our examination. It takes some experience, but will soon be learned by routine practice.

It has often been said that tubercle bacilli have a predilection for the lymphatic glands and the picture of the immense tuberculous glands of the neck is vivid in our imagination. They are not so frequent as they used to be. Fifty-four years ago the Danish physician, Wilhelm Meyer, advanced his adenotomy, which removes the obstructing growth but fortunately not the original adenoid tissue itself. This popular and beneficial operation is un-

doubtedly the chief cause of the reduction in frequency of tuberculous glands of the neck by striking at the focus of entrance. If tubercle bacilli have predilection for lymphatic glands, it must be the same predilection that criminals have for prisons, for the bacilli are carried thither by the lymphatics for imprisonment and destruction. Oftentimes they put up an awful fight, break jail like other dangerous and cunning criminals, pass to the next glands and even jump them to finally get access to the general circulation and appear in distant organs as metastases. But as far as the eye is concerned I am coming more and more to the conviction that metastatic tuberculous affections are more rare than those of ectogenous origin and that there is no need to deviate from beaten path of entrance through the conjunctiva itself.

Probably we have trachomatous irritations of the conjunctiva that do not develop into real trachoma. I have never found preauricular glands in such diseases. Irritation from Morax-Axenfeld's diplobacillus is common; likewise *irritatio conjunctivae* in "colds" and hayfever. We have *irritatio conjunctivae* from light, heat, electricity, gases and smokes. We have *irritatio conjunctivae* from face powders. We have artificial *irritatio conjunctivae* in patients who like to fool the doctor, and sometimes succeed for a while. And so on. But it always remains with the air and what it contains, to be the principal factor and *irritatio conjunctivae* due to refractive, muscular and accommodative errors are unknown to me.

The objective findings in *irritatio conjunctivae* vary in intensity, extent and character. They are often so trifling that they will escape a fleeting examination and be paid no attention. A moderate hyperemia of the conjunctiva of the tarsal plates—general or localized in the angular parts—is usually the first beginning. The tarsal conjunctiva loses somewhat in smoothness and transparency; still the Meibomian glands are visible. By continued conjunctival irritation the tarsal conjunctiva may hypertrophy and present a sandy or velvety appearance and obscure more or less the Meibomian glands. In protracted cases concretions in the goblet cells are not infrequently found. The retro-tarsal folds, which always should be investigated by pressing the globe backwards with the lids everted, one by one, will also often present both hyperemia and swelling, while the bulbar conjunctiva remains unchanged. There is generally some

mucous secretion, and while there may be a little dried secretion in the corner of the eye, there is usually not enough to stick the lids together in the morning. A frequent finding, particularly in children but also in adults, is more or less numerous follicles in the adenoid tissue of the retrotarsal folds. As the lower fornix is a better hiding place than the upper, it is here we find them in the greatest number. Both the caruncula and the semilunar folds may show hyperemia, hypertrophy and even follicles. The edges of the lids may be hyperemic and red as after crying; also seborrheic. The lacrymal puncta may in elder individuals be found small, contracted and even closed, in which case epiphora, which is uncommon in simple *irritatio conjunctivae*, results.

If the subconjunctiva participates in the irritation, the lids may be somewhat puffed and both the bulbar conjunctiva and the subconjunctiva will show a number of vessels running from the inner and outer canthus towards the cornea. The semilunar folds will show a tendency to be drawn forwards. The final result may be pinguecula, pterygium or both. If the Meibomian glands are involved, increased secretion in the form of a white scum in the inner angle is often seen. Pressing the everted lids against each other with glass rods or the fingers will bring out the increased secretion. If the episclera is invaded, we find the deep, bluish, ciliary injection, which can immediately be intensified if we part the lids and expose the eye to the air. The bulbar conjunctiva reddens very little on exposure to the air, while the tarsal conjunctiva does.

If the orbital contents are invaded, we can no longer use our sight. We must use our touch and examine for tenderness. The normal eye is indolent to palpation and pressure. Only the hypersensitive eye may rebel—sometimes even before we touch it. If the orbital sensitive nerves are invaded by the toxins of the conjunctival irritation, tenderness on palpation and more so on pressure will be complained of. The tender eye has received scant attention in the literature. It is to my mind and in my experience such an important finding, that I never consider an examination of the eyes complete without it and the examination itself is simple. Palpate or press the sclera particularly over the insertions of the muscles; after that push the eye against the orbital wall in all the different directions or bore your finger between the eye and the orbital

wall and you will soon find where the shoe presses. The finding of tender eyes is of the greatest importance for the treatment.

The subjective symptoms of *irritatio conjunctivae* vary considerably according to the degree, character and complications of the irritation and the disposition and social status of the patient. A good many people do not mind a little irritation at all. The ordinary complaints are that the eyes smart, itch, burn, feel sore and ache. Some complain that the eyes feel sandy and dry; some have a feeling of foreign body and a desire to wink and rub the eyes. Some are sensitive to bright or artificial light, others to radiating heat from the lamp or the stove. Complaints of eye-strain or asthenopia (conjunctival asthenopia) are general, especially among the "high-strung" and "run down." If the eyes are tender, they will all complain of tiring from near work, of tearing, of blurred vision, that the eyes will not "focus right," and also of headaches—toxic asthenopia and toxic headaches—which will be more felt in the evening by artificial light. The eyes will feel tired, heavy and sleepy.

Tenderness of the eyes is often more pronounced on the one side than the other, and if the eyes are tender there will often be morning headaches, which should not be attributed to eye-strain the preceding day. Tender eyes and headaches from overtaxing alone will disappear over night. Endurance both of accommodation and convergence will suffer in tender eyes. To work with tender eyes is pretty much the same as to walk on tender or lame feet.

TREATMENT

Optical treatment.—I have already stated that *irritatio conjunctivae* from refractive, muscular and accommodative errors is unknown to me. This statement is not in conformity with the general opinion in this country, where the slightest error is held responsible for the symptoms of *irritatio conjunctivae* with the result that every complainant gets his glass. Being an air disease, no glass of any description can prevent or cure conjunctival irritation. Overtaxing of the eye and refractive errors will aggravate the condition by the resulting passive hyperemia, which in turn will patronize multiplication of the bacteria present. The patients should consequently be given the benefit of what optical treatment may be of assistance and help in their work.

The human eye in civilized nations sees, in spite of its congenital optical imperfections, everything

that is necessary, and what our eyes do not see our hearts do not feel. Wild people may see two, three up to five times sharper than we. They may need this much for their existence. We do not need it for ours and we do not feel any envy. The wild man's eye is mainly for distance, which means more or less rest; the white man's eye is to a great extent for near work with strain both on the accommodation and convergence and needs the same rest, after a day's work, that the body does.

The most eyes are born hypermetropic (on an average 1.25 diopter) and also astigmatic (0.25 to 0.50 diopter). When the congenital hypermetropia does not exceed 1 diopter, we call the eye emmetropic or normal, and when the astigmatism does not exceed 0.25 to 0.50 diopter, we used to call it physiologic. In this country all astigmatism is called pathologic and held responsible for the symptoms I have attributed to *irritatio conjunctivae*. However, such a slightly hypermetropic and astigmatic eye should not and will not under ordinary circumstances give trouble, before the individual reaches the presbyopic age and should not need correction for their small imperfections. But they will all be fitted with glasses, as soon as eyes give trouble from hypersensitiveness, overtaxing and irritation. And many of those who are fitted with "physiological" glasses derive real benefit and declare they can not do without them, which is difficult to charge up to the low number, but easier to attribute to the glass as such, to the protection against wind and dust, heat and light, to a habit or to auto-suggestion. But all those who come to me with "unsatisfactory" glasses, that they cannot do without and that I myself cannot improve, I advise to continue with them, but not as a treatment for the conjunctival irritation I usually find present in such cases, but for protection pure and simple. A plain glass would probably do the same and such plain lenses I have in my trial case instead of the fractions of 0.25 diopter and in many cases I have found that plain glasses give the same satisfaction as the low numbers. But since it always is possible to find a low number that will fit, I consequently give the patients the benefit of what little improvement in clearness such a weak glass will bring. On the irritation itself these weak glasses have no influence.

The belief in the almighty glass has become so ingrown in the people that they go to the specialist, the optometrist, the optician or the traveling refrac-

tionist to get glasses when troubled with their eyes and head; only a small minority hope that it will not be necessary to be fitted. Each eye is tested and corrected separately and the patients are told to wear the glasses all the time. If the glasses don't prove satisfactory, the doctor says that the eyes have changed; but the next correction is no better. Another doctor is consulted; he must go his predecessor one better, but fails. And so it often happens that a patient presents himself with his pocket full of glasses,—all of them very much alike and of the lowest numbers and usually different for each eye. This is an almost daily experience. Not seldom has the patient been overcorrected after skiascopic examination on the dilated pupil with accommodation paralyzed and has gotten presbyopic glasses with reduced distant vision; and all of them are dissatisfied with the new condition of affairs.

The success of refraction work as such does not depend upon compelling the patients to wear constantly the glasses the doctor has in his wisdom prescribed. The patient is the last and real judge, and when he is not satisfied, while the glasses in themselves may be correct, I draw the simple conclusion that it is not a glass he needed but a medical treatment for what in the most cases will appear to be conjunctival irritation, which has not received any consideration or been overlooked. Irritation or no irritation, I am always of the opinion that people working under electric light should have "physiological" glasses for protection and that people exposed to wind and dust, or occupied with milking, harvest work or threshing should have glasses for temporary protection.

Since our eyes are not optically perfect, the professionals believe they should be rendered as perfect as possible with glasses and there is nothing to say to that—let people have what they want. But when glasses are indiscriminately prescribed for the treatment and cure of all possible eye troubles, it becomes a public nuisance. Every individual will become an eye-patient, if he lives long enough; but to consider every individual a born eye-patient, that shall have a glass as soon as a professional gets hold of him, shows certainly a sense of business but lack of understanding, experience or judgment. No wonder that so many people after awhile throw off their glasses, when they understand that they neither help nor beautify. Fortunately superfluous or even wrong glasses never

cause any injury to the eyes, only discomfort, besides being a costly experiment in the present times. It is not uncommon among the people to blame the glasses for having spoiled their eyes. This is unjust and I always tell them so frankly. Glasses are not made for health or decoration, but for comfort and protection.

The eminent Danish oculist, Edmund Hansen-Grut, a pupil of Graefe, wrote some fifty years ago, when fitting glasses in all possible eye troubles began to be an epidemic, that if the doctor would pay more attention to the patient's conjunctiva, he would generally find some catarrhal trouble and that treatment for this would make glasses superfluous and save a fortune. I felt guilty at the time, sat down and took notice and have remembered it ever since with increasing conviction of the truth of it. Still I often prescribe protection glasses as already stated. I never prescribe glasses that dim the distant vision and enlarge the print. And when I find that the patients have been overcorrected and got presbyopic glasses, I always change them, if the glasses have not already made them presbyopic, when they may need them for near work.

When I myself so often have disappointed my patients in my refraction work, which I have been at for fifty years, I do not hold my methods—the ophthalmometer, the ophthalmoscope and the subjective examination—responsible, although this examination in the American eye is unsatisfactory, as it does not include skiascopy on the dilated pupil with accommodation paralyzed. When I slip, it is either because my judgment has not been good or because I have overlooked or underrated the conjunctival irritation and missed the tender eye or that I have run up against hysterical and neurasthenic women whom nobody can please (*copiopia hysterica*, Forster). *Donna é mobile*. (*Rigoletto*.)

Local treatment.—A local disease requires a local treatment and generally people with *irritatio conjunctivae* not only get glasses but at the same time a prescription for simple lotion or eyedrops or salves. Salves do not do as well in conjunctival irritation as solutions. Their place is on the lids and their margins. To clean out and disinfect the conjunctival sac must be our aim. For cleaning out there is no better remedy than salt, boric acid or baborate of sodium solutions, all of which are non-irritating placebos that work mechanically and should be used in an eye-cup (mechanical house-cleaning). For disinfection of the conjunctiva we

have zinc, quinine, the different silver preparations, copper, alum and mercurial preparations, as calomel, sublimate and, last but not least, mercuriochrome. The disinfectant for the conjunctival irritation should preferably be as little irritating as possible. Therefore, nitrate of silver in 1 to 2 per cent solution has no place here. The other silver preparations I have long ago discarded, as I believe we have better chemicals at our disposal. The oldest, tried and most popular disinfectant or astringent, as it is called, is sulphate or chloride of zinc, which is claimed to have a specific action on the frequent Morax-Axenfeld's diplobacillus irritation and helpful in others. It is difficult to understand how a couple of drops instilled once or twice a day in the conjunctiva, which cannot hold even one drop and from which the drops are immediately expelled, can be of real antiseptic value. When experience nevertheless has proven the beneficial influence of such drops, many believe there must be some sort of biological action—chemo-biological action. If to zinc solutions is added adrenalin and cocain we have a really wonderful eyewater with increased action of zinc and with immediate relief from the astringent adrenalin and the anesthetic cocain. We are warned against the routine treatment with cocain. I myself do not know that I have ever seen anything that should prevent one from adding 0.5 to 1 per cent cocain to the solution. Adrenalin can be added freely, up to 50 per cent. I always add a little bisulphate of quinine to the zinc solution to increase its antiseptic properties. This gives the solution a beautiful fluorescent, bluish color. Such an eyewater or eyewash is very popular among my patients with *irritatio conjunctivae*. The only trouble is that they cannot refill the bottle without a new prescription. I have been so satisfied with this solution that I have not tried Butyn, which is non-narcotic and which does not require new prescriptions. For the same reason I have no experience with resorcin, while I sometimes touch the patient gently with alum and copper pencils.

A great man—Fuchs—writes great words about “collyrium adstringens luteum” (Horst's Eyewater)—“that it gives excellent success and is in many instances not to be replaced by any other.” It is a mixture of chloride of ammonium (0.4); sulphate of zinc (1.0); dissolve in 180 grams distilled water; add camphora (0.4) dissolved in dilute alcohol (20); add crocus (0.1), macerate through

24 hours, shake often and filter. Dilute it for use with 50 per cent distilled water. Having tried this for *catarrhus senilis*, I prefer a 1 per cent solution of mercurochrome, the new Baltimore germicide, which I have already mentioned in a paper on "herpes corneae" last year and which I will take the opportunity to give a special mention.

The originators of mercurochrome—prominent Baltimore urologists and chemists—have designated it "a general germicide, deeply penetrating, non-irritating, of low toxicity and of relatively quick action." It was originally intended for urological purposes, but was soon adopted and praised by the eye, ear, nose and throat men. I began using it for sterilizing the eye before and after curetting the cornea in *herpes corneae*. But I did not use it for daily treatments for fear it might be a cell poison and retard epithelization. Being a powerful antiseptic it is consequently not an epithelial food, but being of low toxicity the possible retardation of the epithelization is counterbalanced by the fact that it assists materially in keeping the eye aseptic, thus favoring the epithelization rather than retarding it. I have learned to know that mercurochrome is the simplest, safest, quickest, deepest and least irritating antiseptic we have for ophthalmological purposes—but not the most powerful; neither is it omnipotent. Thus in serpentine ulcers of the cornea, where we have no time for experimenting, I don't trust it alone even with frequent instillations up to 5 per cent solutions. But I do believe that any corneal ulcer during harvest time or threshing season should be immediately and repeatedly treated with 2 per cent solution of mercurochrome and I feel confident that this dreadful disease which causes the loss of so many eyes could be checked. Since we do not have a surplus of useful antiseptics, mercurochrome has been most welcome to me. We need a variation, since the eye will get used to one and the same remedy, which will lose in action. I experimented both with acriflavin, and proflavin, before I got hold of mercurochrome. They were good, non-irritating antiseptics, but hold no comparison with mercurochrome in my experience.

Mercurochrome is a mercurial compound with an intense, beautiful red stain. As this stain, which sticks long and has been difficult to remove, has been objectionable both to urologists and oculists, the same Baltimore men have lately presented us with another mercurial compound with "invisible" stain,—meroxyl. But in ophthalmology it cannot

replace mercurochrome, for it is said by the originators to be certainly a more powerful antiseptic but at the same time more irritating and toxic and less penetrating. I hardly believe it has any future in ophthalmology in spite of being non-staining. I personally have no particular objection to the mercurochrome stain; neither have my patients. It is true that red eyes and a red nose never have been considered decorative; but it is also true that the red stain from mercurochrome on the lids and face can quickly be removed by cold-cream or noviform ointment, and the conjunctival and corneal stain soon is removed by the tears or by any eyewater which contains cocain or, still better, holocain, which immediately will precipitate the stain, which henceforth will be removed by the tears. To control the staining of the face, I always make the instillations with the patients on their backs, protecting the face on either side with gauze.

Far from objectionable, I consider the stain itself a wonderful thing for immediate diagnosis of even the minute epithelial defects which it will color intensely for some time and which often are overlooked if not stained. We have heretofore used fluorescein for demonstrating epithelial defects in the cornea; but mercurochrome is much simpler and better, both for conjunctiva and cornea, and has in my practice replaced fluorescein entirely. If no epithelial defects, the natural or increased mucous film on the conjunctiva and cornea will only be passingly stained.

Mercurochrome is claimed to be non-irritating. It would be wonderful if true. It seems inconceivable that such a powerful germicide should be so. Still it is a fact that mercurochrome in 1 or 2 per cent solution, put into a normal eye, scarcely reacts on the victim. Thus, in disinfecting a normal appearing conjunctiva, preparatory to cataract operation, the patient experiences hardly any irritation. But if the conjunctiva is irritated, which is usually more or less the case in old people, and if the patient at the same time is hypersensitive, which old people sometimes are, smarting sensation will follow instillation, lasting usually a short time, being moderate in degree. I have seen cases of *irritatio conjunctivae*, where the eye after instillation with mercurochrome has burned like fire and caused so much misery that relief by cocain or holocain was appreciated. Such cases are, however, exceptions to the rule. Mercurochrome is not more irritating and for no longer time than anybody can stand

without kicking and consequently I have up to this time not disposed of it in any case and neither has anybody asked to be excused. I have never seen idiosyncrasy for mercurochrome or permanent staining. I further think that mercurochrome is a pretty reliable test not only for the degree of irritation, but also for the existence of irritation which the patient might not be conscious of himself. If mercurochrome produces only a moderate, temporary discomfort, no cocain or holocain should be instilled, in order to give the antiseptic full sway, and it can be properly instilled one or more times a day in any conjunctival, corneal or lacrymal trouble. In simple conjunctival irritation, once a day is sufficient.

Usually I give the patients prescriptions both for 1 per cent mercurochrome and for the named compound zinc solution from a stock solution, the formula of which is printed on the back of my prescriptions (boiling water 1000; glycerite of boroglycerine 50; quinine bisulphate 1; zinc sulphate 5; hydrocyanic acid, dilute, 15); cool and filter. For eyewash I add 10 per cent adrenalin and 0.5 per cent cocain; for drops I add 30-50 per cent adrenalin and from 0.5 (children) to 1 per cent (grown) cocain. If a couple of the "red" drops irritate, I advise to put in a couple of "white" drops afterwards; always in a recumbent position, in the corner of the eye with subsequent winkings or pulling down of the lower lid. Oftentimes I alternate—"red" drops one day and "white" drops the next. In old people I also prescribe Horst's eyewater for a change. Both the "white" and the "red" drops will deteriorate in time, for which reason I do not prescribe more than 30 grams at the time. Fuchs advises against putting in drops at bedtime, but he does not give any reason.

If there is only *irritatio conjunctivae*, the patients get along very nicely with the "white" lotion or drops and with the "red" drops. I never prescribe mercurochrome for eyewash, which requires sitting position and a towel. As the *irritatio conjunctivae* is a more or less chronic condition, often obstinate, I advise my patients to stick it out and not to drop the treatment too soon and to always have the remedies on hand.

In complications with subconjunctival irritation, which usually comes later and which is more chronic, troublesome and obstinate, the treatment is the same as for simple conjunctival irritation. In such cases I also try my way with salve—2 per

cent yellow oxide of mercury or 5 per cent noviform ointment. With a glass-rod I put some salve into the conjunctival sac, followed by a good rubbing or massage of the eye. Often the salves are not tolerated and must be dispensed with.

Red, squamous margins (seborrhea), which should always be looked for, should be treated with salves as the chief remedy. The salves should be as little irritating as possible. At this time I know of no better ingredient than noviform, made into an ointment with equal parts of distilled water, white vaseline and anhydrous lanolin, which is a cleaner product than the ordinary lanolin. The salve should contain from 3-10 per cent noviform. The best time for applying this salve is at bedtime. After good rubbing, the excess salve should be removed with the eyelids pinched together so that an anointed margin will be left for the night. If applied in the morning, all traces of salve should consequently be wiped off. I further advise to pluck out all loose hairs in the morning. Sometimes the vaseline itself is irritating. In such cases cold-cream may do better.

If the Meibomian glands are involved, the increased secretion can be removed either by lid massage or by pressing the upper and lower tarsus against each other on everted lids.

If the canaliculi, the tear sacs and the lacrymal canals participate in the trouble, if there is any epiphora, which very seldom results from simple conjunctival irritation except in hypersensitive individuals, the patency of the lacrymal ducts should be tried with instillation of 2 per cent mercurochrome in the recumbent position under vigorous winkings. If the system is patent, the handkerchief will soon show red stain. This test only shows that the system is patent, but not to what degree; it must be easy permeable to tears if epiphora does not result. Even the normal eye will tear in sharp air and wind. A simple hyperemia of the canaliculi is enough to hinder the tears from passing easily. Therefore, if the local treatment of the conjunctival irritation does not stop the epiphora, I slit the canaliculi to the opening into the sac, making a complete gutter of them. While there is hardly any bleeding from splitting a normal canaliculus, a hyperemic canaliculus will bleed freely. Often I find more or less stenosis in the canaliculi and even complete obliteration of the puncta. The epiphora will stop, provided there is no obstruction of the lacrymal canals, which, however, often is

the case. For this test I use an ordinary eye-dropper with a pointed, smooth tip, which I make myself and which at the same time allows a free stream. If the lacrymal canals are open, but little pressure on the bulb forces the water easily through. If that is not the case, I probe and dilate the canals with Theobald's probe No. 7 and 8,—only once as a rule; after that I let a syringeful of 1 per cent mercurochrome run through, with repetition every day. Next day the solution may not get through, but it often will during the next days without further dilatation, which, however, may have to be repeated. If there is real dacryocystitis present, I continue the instillation and injection with 1 to 2 per cent mercurochrome and since I have begun with this treatment, two years ago, I have never been compelled to operate on the sac one way or the other.

I am sighing now that I take up the treatment of the tender eye and headache. Up to now, I have held the conjunctival irritation responsible. I have not crossed the stream for water, but I may not have seen the woods for trees. When the accessory sinuses—the troublesome neighbors of the orbitae with their precious contents—gained such reputation that everybody with a cold and headache spoke of sinus trouble and the rhinologist let the oculist know that it would be to his advantage to consult the rhinologist before putting glasses on for aching eyes and headaches, I was so impressed by the idea that I referred everybody with tender eyes or headaches to my rhinological brother. Through blood-vessels, lymphatics and nerves the orbits communicate with the nose. The usual report was, that there was either nasal irritation, deviated septum, atrophic or hypertrophic catarrh, crowding on one side or the other, polypi or clear sinuses. The headaches were explained as vacuum headaches.

The nose, which inhales contaminated air day and night and exhales it again free from all contamination (Tyndall), tries to rid itself of the impurities which have settled down upon the mucous membrane, through blowing with a handkerchief or the finger. The rich man puts the product in his pocket, while the poor man gives it back to the earth from which it came. The result for the nose is the same, but there is lots left and colds in the nose and head are therefore a very common thing. That toxins from the mucous membrane of the accessory sinuses may invade the orbit through their thin bony walls and often do is beyond all

question. Real infections from the accessory sinuses have also at times invaded the orbit. How much of the tenderness and headaches in a given case should be attributed to the sinuses and to the existing conjunctival irritation is consequently impossible to say. It is possible that nasal irritation may pass through the lacrymal ducts into the conjunctiva and produce conjunctival irritation. This is, however, against the stream and is certainly rare. This is a disputed question at any rate. But whether the conjunctival irritation comes from the nose or originates in the conjunctiva, the fact remains that tenderness of the eye and headaches due to the orbital tenderness remain in spite of rhinal treatment, which should always be tried and which so often is beneficial to the patient's nose and attributes. Therefore, I shall continue to refer my patients with tender eyes and headaches to the rhinologist.

Tender eyes and headaches may also result from general conditions,—from rheumatism that troubles so many people in middle and advanced years. They may also result from supraorbital neuritis, not only ascending from the conjunctiva or the accessory sinuses, but also descending from intracranial or other causes. The region of the supra-orbital nerves is often the most tender spot. Tenderness and headaches from simple hypersensitivity alone is certainly not uncommon; it runs in the family. But, on the whole, I do believe that tender eyes and headaches most frequently are the direct result of conjunctival irritation. Not all patients with tender eyes complain of headaches, but all of them complain of asthenopia or eyestrain.

I have often found some relief from occasional use of headache tablets. I have found them to be better than aspirin, which is so advertised, so often resorted to and also prescribed for all kinds of headache. The special local treatment I most rely upon is rubbings and massage of the tender eyes. Some people are afraid of rubbing their eyes. I don't think the doctor told them so. Rubbing of the eye, which so many with conjunctival irritation and tender eyes feel like doing and also do, may be an instrument to press bacteria and other irritating elements into the subconjunctiva; but as there are always two sides to every question, rubbing may also be an instrument to drive the obnoxious elements out of the conjunctiva, for which reason I unhesitatingly and without regret have recommended not only general rubbing of the eye through

the lids in the usual way (we all do it), but also special massage of the tender spots with the fingertip wherever they are found, keeping it up gently until the tenderness is gone, which always results. If the patient would make a routine of such massage, he would soon learn to do it both properly and effectively. It is particularly recommended when the eyes have tired from near-work, when the eyes blur, the tears begin to come and the eyes and head ache from accommodation spasm and convergence. That is the time to take a little rest, lay off the glasses, if any, and spend a few minutes on the eye. The most tender spots will usually be found in the region of the ethmoidal and frontal sinuses, the supraorbital nerve and the inner recti muscles; also back of the eye, when pressing the eye backwards in the direction of the sphenoidal cells. Such massage hurts often more in the one eye than in the other, which might be perfectly free. Therefore be not too rough; all massage should be done with gentle fingers. Then go to work again. The oftener the eyes are massaged, the better.

Massage is a good adjuvant in the treatment of tender eyes from nasal, conjunctival or combined irritation and will always give relief if carried out for a long time, which I believe comparatively few people have patience to do; while hunting for curative glasses in otherwise normal eyes is like hunting for a needle in a haystack, I don't criticize the honest and conscientious doctor who wants to give the patients the benefit of the doubt. The people want glasses and let them have what they want; but let them particularly have the benefit of local treatment.

There is a natural cure for every disease. Unfortunately, people die while the cure is going on. There is also a natural cure for tender eyes and headaches and old people are really little troubled with any of them. Headaches is not an old man's or woman's trouble.

General treatment.—I always inquire about the general condition of my patients with conjunctival irritation. Children with conjunctival irritation, numerous follicles which by themselves many times do not cause any trouble, and with preauricular glands, and glands on the neck, I always refer to the nose and throat man with a plea to respect the tonsils, which are there for an important purpose and which should not be sacrificed unless they continually are so diseased that they are not amenable

to local treatments and the conclusion is drawn that they do more harm than good. Troublesome adenoids I like to see removed. I prescribe the old Iodide of Iron for internal medication in the anemic and scrofular; I further advise a vacation spent in the country away from the roads, preferably where there are woods, plenty of butter and fresh milk.

With conjunctival irritation in grown people, I always like to examine the urine and also to take the blood-pressure. What I examine for in the urine is not particularly albumin or sugar, but the specific gravity, color and toxicity (chromaturia indicanuria). A pale urine of low specific gravity means ordinarily nervousness in females and beer in males. Nowadays a man's urine is seldom pale, deplorably. The pale urine in girls tells me why they suffer more from the inconvenience of conjunctival irritation than men with normal specific gravity. They are invariably neurotic and hypersensitive. The toxicity of the urine from alimentary sources is very simple and easy to demonstrate by pouring some 70 per cent nitric acid into a small conical glass, half filled with the patient's urine. Between the heavier acid on the bottom and the lighter urine on the top there immediately appears, with great regularity, a zone of different colors with greatest intensity after a minute or two. A pale urine will give very little color zone; a normal urine—for instance, your own—will give more, and when the examiner has satisfied his mind what is normal and subnormal, it will be easy for him to judge the degree of increase. If albumin is present, it will appear directly above the colored zone. If the urates are increased, another white sharp ring will appear above the albumin (high and low ring). Increased toxicity of the urine (sapremia) requires a cleaning out to find out if it is only of passing nature. If it persists, a diagnosis should be made; but this does not belong here. Increased toxicity in old people means usually "weedy" colons and they cannot be weeded out with diet, medicine or with Metchnikoff's Bulgarian milk treatment. I let them eat or drink what they like and what agrees with them. Such chronic intestinal sapremia may be one of the causes of early senility with high or low blood-pressure; it may also be one of the causes of "rheumatism" of the eyes as well as the body; but we do not need to look upon it as a cause for "catarrhus senilis." I think these old people do much better with a general

nerve tonic, than with anti-rheumatic medicines and iodides. Thus my experience runs at least. So I give these old people what benefit there is in continued use of a favorite prescription I have adhered to for many years: Tinctura Nucis Vomica 50; Phosphoric Acid (dilute) 100; Tinctura Gentianae Compositae ad 500. Sig: A teaspoonful in a wine-glass of water before meals. This I give them whether the blood-pressure is high or low. It is a good prescription for old people,—a “pep” or “rejuvenation” preparation.

In pale, worn-out girls with pale urine, I like to take the hemoglobin test. If the coloring is below 70, I give them the same medicine, which they usually soon get used to in spite of its bitter taste. It works better than the same combination in “sugar-coated” pills. The mixture stimulates their appetite and gives them all the iron from the food they need. I have for many years turned my back on iron preparations without denying their usefulness in cases of anemia.

In sending out this humble message to the medical profession at large, I fully realize that I have not solved any medical question to universal approbation. It is only my personal views after fifty years' experience that I have expressed. Medical science is as infinite as the universe. The last word has never been and never will be said or written.

MANIFESTATIONS OF FOCAL INFECTIONS IN THE RESPIRATORY, CIRCULATORY, URINARY, AND GASTRO-INTESTINAL SYSTEMS IN INFANCY AND CHILDHOOD*

F. C. RODDA, M.D.
Minneapolis

The idea of focal infection is not new. Eyerlin in 1789 appreciated the relationship of tonsillitis and rheumatism. Benjamin Rush¹ in 1818 reported a case of rheumatism of the hip cured by extraction of a carious tooth. The principle of focal infection as a cause of acute and chronic systemic disease has now been fully accepted. It is made the basis for a large proportion (estimated as high as 70 per cent) of present medical prac-

tice. Credit for placing this work on the firm scientific foundation of today goes to Billings and Rosenow.

Billings² defines a focus of infection as “a circumscribed area of tissue infected with pathogenic organisms.” Foci may be located anywhere in the body—most often in the mouth, its communicating cavities, and regional lymph structures. At times a focus may be located in a most unexpected quarter. A great many pathogenic organisms have been found as offenders, those heading the list in frequency and importance being members of the streptococcic and pneumococcic groups. Systemic disease results when pathogenic organisms, their soluble toxins, or their debris set up pathologic changes in tissues or organs which may be contiguous to, or far removed from, the original site. Transportation occurs by hematogenous or lymphogenous routes. The list of diseases caused by focal infections is already too long for recital. Undoubtedly others will be added in the future.

With this very brief statement of the principles of focal infection we may proceed to our topic—Manifestations of Focal Infections in the Respiratory, Circulatory, Gastro-Intestinal and Other Systems. On these subjects volumes have been written, mostly, however, on studies concerning the adult; little has been done on infants and children. I can only briefly touch on a few of the disorders of infancy and childhood.

MANIFESTATIONS IN THE RESPIRATORY SYSTEM

During three-fourths of the year, in this latitude, respiratory infections provide the bulk of our everyday work. To the casual observer many of them are more or less trivial. However, bronchitis, broncho-pneumonia, lobar pneumonia, pleurisy, and empyema contribute heavily to infant and child mortality. These conditions, so often fatal, are rarely, if ever, primary—they are practically always secondary to infections higher up. Our wave of serious lung diseases occurs late in the winter and in the spring. It is preceded by waves of milder upper respiratory infections such as rhinitis, pharyngitis, tonsillitis, otitis, etc. What rôle does focal infection play in this? We believe a large one.

Repeated infections of lymphoid tissue and sinuses in and adjacent to the respiratory passages lead to: (1) loss of weight, anemia, and general

*Presented before the Southern Minnesota Medical Association at Faribault, June 11, 1923.

debility in our little patients; (2) lowered resistance to bacterial invasion; (3) increased virulence of infecting organisms.

The stage is now all set for a serious illness which may follow a new infection, or if infection is already present may follow indiscretions in exercise, diet, clothing, etc.

I wish especially to emphasize the latter factor. We have just gone through a cycle when drafts and chilling as determining factors in infection have been scoffed at. But with our present mode of living we know that chilling of body surfaces profoundly affects the circulation in mucous membranes, predisposing to infection. Rosenow has also shown that chilling may increase the pathogenicity of bacteria in the tissues.

We feel, therefore, that removal of proved foci of infection along the upper respiratory tract will prove extremely valuable as a prophylactic. Our efforts should not be limited to surgical interference. Diet, cod liver oil, rest, and heliotherapy are valuable adjuncts.

ASTHMA AND FOCAL INFECTION

It may be true that asthma is most often an anaphylactic reaction to foods, pollens, dust and bacterial proteins. Walker³ has shown, however, that in the absence of positive protein tests the removal of foci of infection about the teeth and in tonsils may prove curative. Oftedal⁴ has shown that rabbits injected with streptococci from asthmatic sputum present foci of infection in the bronchial musculature.

A critical survey of an asthmatic must therefore include a search for focal infection as well as the performance of sensitization tests.

THE CIRCULATORY SYSTEM

When free from congenital defects the heart in infancy and childhood is peculiarly competent for its work. Changes resulting from sclerosis of vessels and chronic kidney pathology with resultant hypertension are rarely if ever met with in early life. Heart disease in children is preeminently a manifestation of focal infection. The relationship of tonsillitis, rheumatic fever, chorea, and heart disease is recognized by all. The experimental work of Rosenow⁵ adds scientific proof of the correctness of clinical observations. It would be superfluous at this time to carry the discussion to further detail.

I should like, however, to make a few observations as applied particularly to children's work.

1. Caries and abscesses about the deciduous teeth may be the cause of heart disease; therefore the same care should be given the first set of teeth as is awarded the permanent set.

2. The early removal of foci of infection in children often gives most gratifying results in heart disease. More may be expected than in the adult where long continued infection has produced chronic degenerative changes.

3. If not in acute decompensation the heart stands the anesthetic and surgical attack, incident to the clearing up of foci, unusually well. Murmurs may be disregarded in considering operative risks.

4. Paroxysmal arrhythmias (tachycardia) do rarely occur as the result of focal infection in the child. The exhibition of quinidin and allied drugs should not precede search for foci of infection.

5. Though difficult of statistical proof as yet, I feel our knowledge of focal infection and its appropriate application has greatly reduced the incidence of heart disease in childhood.

MANIFESTATIONS IN THE GENITO-URINARY SYSTEM

A. Nephritis.

In children the typical form of nephritis from focal infection is the acute glomerulonephritis: the mode of infection is hematogenous; the symptoms—lessened quantity of bloody urine, albumin, casts, and a soft edema. The attempts to demonstrate bacteria, presumably streptococci, have not met with much success. Grulee⁶ reports bacterial studies in six cases, and more recently Hill⁷ in twenty-one cases. Hill suggests an explanation for the failure to find the organism in the fact that cultures of the urine were not made at the onset of the disease. He also raises the question whether the kidney might not suffer from a soluble virus or toxin.

We do, however, recognize the clear-cut clinical picture of a chill, fever, leucocytosis, and other symptoms of an acute infection to be followed in a few days with bloody urine and the findings of an acute nephritis. In the sequence of events it is also the usual thing to find a focus of infection in an acute tonsillitis, otitis media, mastoid abscess, or cervical adenitis. We have all also seen a rapid subsidence of the nephritis after drainage of ab-

cesses at these sites, or removal of diseased tonsils. So, though bacteriological proof may be lacking in most cases, from clinical observations we must look for foci of infection in every case of acute nephritis in children.

B. Pyelocystitis and Pyelonephritis.

This is one of the most frequent diseases of infancy and perhaps one might say one of the least understood. It is a disease presenting the signs and symptoms of an acute infection—the presence of pus and the colon bacilli in the urine. It has therefore been assumed that the disease is due to an invasion of the kidney pelvis and kidney tissue with colon bacilli which gain entrance by one of three routes:

1. An ascending infection through urethra and bladder.
2. By lymphatic channels from the bowels—a normal habitat of the colon bacilli.
3. Through the blood stream.

Proof is accumulating that the disease is the result of focal infection. May I cite an illustrative case? A little female child entered the University Hospital with a severe pyelitis which cleared up after some weeks. An acute tonsillitis precipitated a sharp return of the pyuria, which again cleared up after some weeks. Thinking it good evidence of focal infection we advised removal of her tonsils. Removal of the tonsils and adenoids was immediately followed by a return of her symptoms, which again cleared up after a few days' treatment.

The idea of this disease being the result of focal infection appears illogical since the organism practically always found is the colon bacillus, and this organism is not found in oral sepsis nor infections of tonsils, ears, cervical glands, etc. However, the work of Bumpus⁸ furnishes almost indisputable proof that in pyelonephritis the streptococcus is the primary invading organism, which is quickly replaced by the secondary colon infection. This fits in with Hill's observations and again explains why a colon bacilluria may persist after symptomatic recovery from a pyelitis.

It would therefore seem wise to search for foci of infection in all cases of pyelocystitis.

MANIFESTATIONS ALONG THE GASTRO-INTESTINAL TRACT

In the adult the principle of focal infection has been accepted at least in part, *e. g.*, gall bladder infections. In children little has been done experi-

mentally, though clinically we recognize certain manifestations. Time, however, permits little more than their simple tabulation.

1. Cyclic Vomiting.

This disorder is often typically the result of focal infection. In the majority of cases the onset of an attack stands in close relationship to an upper respiratory infection. Conversely the removal of these foci, for instance, diseased tonsils, results in a high percentage of cures. Taylor's⁹ figures confirm this assumption. In some cases the focus of infection is found in the appendix, gall bladder, or kidney.

2. Gastric and Duodenal Ulcer.

Though this field is obscured by the smoke of the perpetual battle between the surgeon and the internist, it seems safe to conclude that ulcer may be the result of a focal infection. I bring this topic up for discussion, not as further proof, but call your attention to its unsuspected frequency in children. Holt¹⁰ reports ninety-five cases in infancy; Gerdine and Helmholz¹¹ report eleven cases and comment on its infectiousness and epidemic form. Palmer,¹² more recently, comments on its symptomatology. The condition is hard to diagnose, perhaps largely because we have not been on the lookout for the disorder. Careful observations and diagnostic methods will doubtless make it demonstrable when suspected and present.

3. Appendicitis.

We are all familiar with the picture of an acute appendicitis closely following an acute angina. Rosenow,¹³ experimentally, has produced lesions in the appendix in animals by the injection of organisms into the blood stream. Kritz¹⁴ believes that acute appendicitis is always hematogenous and never primarily caused by infection within the lumen of the appendix.

4. Mucous Colitis.

Preston's¹⁵ reports suggest that this disorder may be the result of a focal infection and not of necessity due to primary local disease.

5. Acute and Chronic Diarrhea in Infancy.

A most striking and frequently overlooked manifestation of focal infection is a certain type of diarrhea. Czerny labels it diarrhea due to parenteral infection. If a feeding case does not clear up on a reasonable routine, it might be wise to look for a source of infection outside the intestinal tract.

We have seen a most speedy cure, without change in the feeding schedule, follow drainage in chronic otitis media.

These remarks perforce are sketchy since the field is so enormously broad, but it is hoped that by mentioning the disorders and their presumed, if not proven, relationship to focal infection, that by careful histories, painstaking observations and complete reports we may eventually enlarge our knowledge so as to clear up the etiology of some puzzling systemic disorders of childhood.

GASTRO-INTESTINAL MOTILITY*

JOHN C. STALEY, M.D.

St. Paul

It is well from time to time for physicians to review the published results of work done by those in special fields; this is particularly true concerning the work of physiologists. As new and interesting facts are brought out they are too often published only in journals devoted to special work and are, therefore, not available to the average physician. As a consequence, physicians are accredited with a lack of interest in the results of experimental work and in their application to medicine. It is true that the study of normal function is didactic and to some is likely to be uninteresting. However, a review of the available literature on gastric and intestinal motility was undertaken and it is hoped that a short summary may be of interest to members of the Society.

It is not feasible to consider one part of the gastro-intestinal tract independently of other parts; yet time does not permit a full consideration of the subject and attention will be, therefore, directed more especially to the stomach with special reference to motility and to the control of the pyloric sphincter.

It is obviously unnecessary to discuss in detail the anatomy of the stomach; one or two interesting features only will be mentioned. The first of these concerns the arrangement of the musculature of the stomach walls. The wall is composed of three layers of muscular tissue, covered by peritoneum and lined with submucosa and mucosa. The outer layer of muscle is longitudinal, the middle is circular, and the inner is oblique. The middle coat is said by some authorities to be thickened in the plane of the incisura angularis, where greater demands are made upon the muscle structure. The circular layer terminates on the right by a piling up of the circular fibers to form the pyloric sphincter. The fibers of the inner layer are placed as U-shaped bundles which loop over the stomach immediately to the left of the cardia. The uppermost fibers of this layer run vertically downward over the whole length of the body of the stomach, both on the anterior and posterior surface. Jefferson describes the layer as having its right margin sharply defined,

*Presidential address read before the Ramsey County Medical Society, St. Paul, April 30, 1923.

a narrow band extending from the incisura cardiaca to the pars pylorica. The contraction of this muscle, according to Kauffman, forms a canal underlying the lesser curvature and seen only when liquids and soft foods are taken. Lewis described the canal as seen in the fetal stomach and called it the *canalis gastricus*. As seen by Lewis "it follows the lesser curvature, appearing as a groove when viewed from the inside of the stomach. It suggests a continuation of the esophagus split open toward the gastric cavity, an open canal which may become a tube during its physiological activity by the approximation of its lips." In the adult, all anatomical trace of the canal has disappeared and yet the area functions, in many cases, as a canal and, as stated by Hartung, the first few mouthfuls seem to follow in grooved arrangement along the lesser curvature called the "*magenstrasse*" by the Germans.

The nerve supply to the stomach is from the pneumo-gastrics, the splanchnics and the sympathetics from the solar plexus. The plexus of Auerbach lies between the longitudinal and circular coats of muscle. The plexus is known also as the myenteric plexus and the local reflex, initiated by it, Cannon has named the myenteric reflex. All movements of the stomach continue after its separation from the body. This was shown as long ago as 1886 by Hofmeister and Schutz. Cannon showed that, after division of both vagus nerves and the splanchnics, there was a temporary lessening of muscular movement after which normal peristalsis was restored. These movements he believed to be initiated and maintained by the plexus of the Auerbach. He states that the function of this plexus is to insure an orderly progression of the contents of the gastro-intestinal tract.

The Myenteric Reflex.—While watching a rubber balloon in the small intestine Cannon discovered that if the wall of the intestine was pinched with a pair of forceps, a constriction at that point occurred, and at the same time there was relaxation below. In that way, propulsion of intestinal contents was effected down the tract. These movements he believed were initiated by the plexus of Auerbach and the reflex he called the myenteric reflex. Bayless and Starling were able to demonstrate the same movements under stimulation but preferred to designate the reflex by another term: "the law of the intestine." Cannon was not always able to demonstrate the reflex, the reason for which

could not be explained. Recently Alvarez in over two thousand stimuli applied to the intestines of rabbits was able to elicit the reflex only twenty times. In all other instances there was contraction both above and below the point stimulated. Alvarez believes that these results were obtained because the experiments were carried out upon the normally digesting bowel instead of one distended by a rubber balloon. The experiments are mentioned only to show the uncertainty concerning the nerve control of the gastro-intestinal tract, which, in accordance with the "gradient" theory of Alvarez, is limited to the regulation of tonicity in the muscles and co-ordination of the whole tract. The principal fact to be noted in this connection is that gastro-intestinal muscles will contract rhythmically after all extrinsic nerves have been severed and after Auerbach's plexus has been paralyzed by the application of cocaine or nicotine to the surface of the bowel. Peristaltic waves coursing over the normal stomach during digestion have been described by Cannon, Carmen, Cole, Case, Kaestel, Holzknacht and others. There is very general agreement as to the movements of the gastro-intestinal tract during its digestive phase with the one important exception, namely: the activities of the pyloric ring.

The Pyloric Sphincter.—The theory of the acid control of the pylorus was elaborated by Cannon. It was assumed that when the stomach was empty the pylorus remained tonically contracted. It continued to remain contracted until the ingested food attained a certain degree of acidity, when the sphincter relaxed and a small amount of the mixture escaped into the duodenum. The presence of acid in the duodenum was then supposed to cause a contraction of the sphincter. Briefly stated, acid on the pyloric side opens the ring and acid on the duodenal side closes it.

Carbohydrates, proteids and fats pass through the pyloric ring in the order named. Carbohydrates do not combine with hydrochloric acid. From that fact it is reasoned that the first acid secreted would cause a relaxation of the pyloric sphincter. On the other hand, proteids combine with hydrochloric acid; consequently, there is no free acid present for a considerable time after ingestion of proteids. Therefore, carbohydrates pass through the pylorus before proteids.

This theory has been accepted notwithstanding the fact that from time to time the clinicians have called attention to the fact that the stomachs of

patients having high acidity do not necessarily empty themselves more quickly than those having various degrees of subacidity and to the still more confusing fact that in cases of achylia gastrica the stomach empties most rapidly.

Cannon carried out his experiments upon animals, mostly upon cats. Of late a few men have been investigating the acid control of the pylorus in man.

McClure, Reynolds and Schwartz, in a series of twenty-two cases, passed into the duodenum a duodenal tube to inject acid and alkali, of varying strength. Their findings do not agree with those of Cannon in two essentials: (1) neither acid nor alkali, in any part of the duodenum, affect the opening or closing of the pyloric ring after a barium meal, as viewed through a fluoroscope; (2) differential discharge of food through the pylorus in man does not obtain, as it was found that barium meals of carbohydrates, proteids and fats are alike as to time of beginning evacuation through the pylorus.

Lockhart, Philips and Carlson, in recent experiments, found that in the human stomach there exists a relation between the gastric peristaltic waves and the opening and closing of the pyloric ring. When a peristaltic wave passed down over the surface of the stomach the pyloric ring was open for the escape of stomach contents. Upon the arrival of the peristaltic wave at the ring, it contracted and remained so until the approach of another wave. Cole previously demonstrated the same facts fluoroscopically and from a study of serial radiographs.

Wheeler and Thomas measured the contraction of both the pyloric sphincter and the antrum with an enterograph. They were able to demonstrate that both the pyloric sphincter and antrum show cycles of the same duration. The phases differ but show a constant type of alteration. These findings are not in accord with those of Cannon, who found that the pyloric ring opened and closed irregularly in response to chemical stimulation in either antrum or duodenum. That the control is not entirely one of motility is evidenced by the fact that the time required for the stomach to empty itself is influenced largely by the character of food ingested: for example, if carbohydrates only are given, the stomach will be found empty in three hours; fats require very nearly six hours and proteids almost as long. If fats are mixed with either carbohydrates or proteids, the former delay the

escape of both. Neither acid control nor motility accounts for these facts.

While apparently not undertaken for the purpose of disproving the theory of acid control of the pylorus, the recent experiments of Boldyreff actually do that. He found, as did Pavlov, that the percentage of hydrochloric acid secreted in gastric juice does not vary. Carlson has more recently confirmed the fact. The first secretion of gastric juice in an empty stomach was found by Boldyreff to contain 0.5 to 0.6 per cent hydrochloric acid. This percentage is rapidly lowered, even in the absence of food, to from 0.1 to 0.2 per cent. The lowering is largely effected through the regurgitation of bile and pancreatic juice. Boldyreff found that a high percentage of hydrochloric acid passing from the stomach causes an irritation and reverse peristalsis in the duodenum so that instead of a hurried evacuation of strong acid contents as should obtain in accordance with the theory of Cannon, there is the partial neutralization within the stomach. This mechanism Boldyreff designates as the self-regulation of the acidity of the contents of the stomach.

All that can be said with certainty at the present time regarding differential discharge of food through the pylorus was stated long ago by Pavlov: "That foods pass through the pylorus in the order in which they are liquefied and prepared in the stomach by the digestive juices acting upon them."

Hunger Contractions.—At the end of digestion the peristaltic waves gradually pass over into the hunger contraction of the empty stomach. They are not at once pronounced. The time of onset, after digestion, depends upon the age and physical vigor of the individual. In infants maximum contractions begin ten to sixty minutes after the stomach is empty; in adults from one to three hours. Carlson found that hunger contractions differ from peristaltic waves in that they begin high up on the cardia, while peristaltic waves have their origin just above the pyloric portion. He found that at times the contractions were so deep and rapid as to resemble the colonic peristaltic rush of Meltzer and Auer.

In this connection it should be stated that we are greatly indebted to Carlson and his associates, Lockhart, Dragstad, Philips, and others of his school, for the painstaking accuracy with which they have worked out many problems relating to gastro-intestinal function.

All normal individuals have at some time felt the pangs of hunger. Cannon and Washburn were the first to associate this sensation with muscular contraction of the stomach. Carlson and one of his associates fasted for five days in order to measure the strength of hunger contractions by means of an inflated rubber balloon placed within the stomach. He found the greatest distress on the third day, although there was progressive increase in the strength of the contractions to the end of the fifth day. These contractions are no doubt the cause of epigastric pain which is complained of so frequently by neurotic patients who take food irregularly and in small amounts. Lockhart and Carlson report cases in which very severe epigastric pains were produced by gastric contraction of the empty stomach in hypersensitive individuals. It is interesting to note the manner in which the theory of hunger pains in duodenal ulcer, as described by Moynihan, coincides with the gastric hunger contractions. It appears to be a clinical fact that when an ulcer is located on the lesser curvature it is the cause of less pain than when situated in more actively motile regions. This, of course, would not be true if complications were present. Contractions of the lesser curvature from the cardia to the incisura angularis are more shallow than those over the greater curvature. Kaestle, Rieder and Rosenthal proved this point by superimposing twelve photographs of a single contraction phase of the human stomach. The resulting picture showed but slight movement of that portion of the lesser curvature throughout the contraction. With ulcer in the pyloric region, where the contractions are strong and deep, the pain is the pronounced feature. The same is true when the ulcer is located in the duodenum. This also may be most plausibly accounted for when it is remembered that movements are normally very active at that point. Furthermore, Boldyreff found that acid escaping from the stomach intensifies movements in the duodenum, which at times are most active and may be reversed.

The Gradient Theory.—As previously stated, gastro-intestinal muscle functions independently of its nerve supply. To account for this fact Alvarez has advanced the gradient theory, which is based upon the fact that muscle has independent function and that there is a graded difference in activity from above downward. It appears that Alvarez has taken over the word "gradient" from the field of biology, where it is applied to the

process of development in all forms of life, both plant and animal. Child, in the study of the planarian worm, finds that development proceeds from before backwards and at the point of the greatest cellular activity the head always develops. As development progresses, it is found that the metabolic rate is greatest at the head and lowest at the tail. The metabolic rate is measured by the susceptibility of the embryo to certain drugs, notably potassium cyanide. Child, and also Hyman, believe that oxygen intake and carbon dioxide output are by that method accurately measured.

In applying the gradient theory to the gastro-intestinal tract, Alvarez has carried out a series of experiments over a period of several years. He has found differences in contraction rhythm of muscle as well as differences in irritability, in tone, in latent period, and, most important of all, a difference in metabolic rate. In each case, the result always depended upon the section of the intestine from which the specimen was taken. Activity progressively lessens from above downward. For example, the irritability of the muscle at the cardia was found to be greater than that at the pylorus and the irritability progressively lessened from the duodenum to within ten inches of the cecum. The same was found to be true concerning the degree of rhythmic contraction of muscle fibres. The power of independent rhythmic contraction was demonstrated by experiments upon fibers on the inner surface of the circular layer in which no remnants of Auerbach's plexus are to be found. When placed in oxygenated Lock's solution the fibers begin and continue for some days a rhythmic beating, the rate always depending upon the section of the tract from which the fibers were taken.

Alvarez believes the pace-making region for the stomach is high up on the lesser curvature, where the greatest irritability, as well as the highest rate of rhythmic contraction, has been noted.

These findings appear to offer some explanation for the reason that V-shaped excisions of the lesser curvature cannot be made without interfering with the emptying power of the stomach as was pointed out some years ago by W. J. Mayo. The truth of this statement has since been attested to many times by surgeons who have attempted the procedure. This theory appears to offer a solution for some other things which have heretofore remained unexplained.

Alvarez states that an ulcer near the pylorus

raises the irritability of that region to a point above that of the cardia with a consequent reversal of the gradient. This results in a delay in the emptying time of the stomach when no real obstruction is present. Again, the behavior of the bowel musculature in intestinal obstruction supplies evidence in support of the theory; if, as the author states, irritation or injury to the bowel will depress or reverse the gradient, it explains why the section of bowel immediately above the obstruction contains only gas and it offers an explanation for the cause of dynamic ileus, that one is at least able to understand.

In conclusion the work of Professor Keith should be mentioned. After a minute dissection of the plexus of Auerbach in many different regions of the gastro-intestinal tract, he was able to convince himself that each of four zones is controlled by a large group of ganglia cells situated within each zone. The theory is of interest because of the eminence of the author, but unaccompanied as it is by physiological studies a detailed résumé of his work will not be made.

CONCLUSIONS

1. The time of opening and closing of the pyloric sphincter is probably not influenced by hydrochloric acid but is governed by the same motor mechanism which controls peristaltic waves during digestion. Hydrochloric acid is an important ingredient of the gastric juice. It liquefies and prepares the food and in that way is an important element in controlling the differential discharge through the pylorus.

2. There is evidence to show that acid causes contraction in the duodenum. The contractions may be reversed, and when they are, the alkaline secretion present in the duodenum is forced backward into the stomach, reducing the acidity.

3. Hunger contractions coursing over a stomach may be the cause of distress or even pain. If there are pathological lesions present the epigastric pain may be intense. The pain is greatest in regions where contraction waves are deepest. Peristaltic waves do not cause the same degree of pain because of the presence of food in the stomach, which prevents an extreme degree of contraction.

4. Gastro-intestinal muscle has the power of rhythmic contraction, even when separated from its nerve supply. Auerbach's plexus is, therefore, a conductor and is not an initiator of stimuli.

5. In accordance with the gradient theory a bolus of food passes from above downward for the reason that pressure is greater above than below the bolus, due to contractions of myogenic origin.

6. The gradient may be depressed throughout the length of the intestinal tract because of illness. A single segment may have an increased rate of rhythmic contraction because of some irritation in the region of that segment. Reversed peristalsis with complete obstruction may result from a local intestinal injury.

DIAGNOSIS OF CONDITIONS ASSOCIATED WITH SPLENOMEGALY*

H. MILTON CONNER, M.D.

Section on Medicine

Mayo Clinic, Rochester, Minnesota

In nearly all conditions in which the spleen is diseased, it is enlarged sufficiently to be palpated at the costal margin. It is also usually true that a palpable spleen is the seat of disease, except in children, or in the comparatively rare instances of prolapse of the organ. Because of the spleen's physiologic function of blood destruction, this function in disease is often exaggerated and leads to severe anemia.

Even careful examiners often overlook the abnormal condition of the spleen. It may be mistaken for a tumor of the kidney, or for a mass in the retroperitoneal region. A well trained finger is necessary for the detection of the rather soft palpable spleen; if it is hard, with a sharp edge, it may be easily recognized. If it is not palpable by examination in the ordinary position, it may be palpated by having the patient lie on the right side doubled up, much as one lies in bed on a cold night, but with the abdominal muscles relaxed. Obviously the notch makes the spleen distinguishable from tumors of other organs, but this cannot always be felt. An important point in the diagnosis is that the spleen seems to come out almost flush with the costal margin, while a tumor of the kidney or one in the retroperitoneal region may appear to leave a sulcus between the costal margin and the tumor when inspiration forces it down. The spleen usually overrides other organs, while the colon is in front of a renal or retroperitoneal tumor, as recognized by tympany on percussion. Percussion and, par excellence, auscultatory percussion, is a much neglected but valuable method in diagnosis. Palpatory percussion and ballotement are of great value in cases of ascites.

In discussing the differential diagnosis of the conditions associated with splenomegaly, only a few of the main points in the diagnosis of each will be considered.

Cases of splenomegaly may be classified into acute and chronic; I shall discuss here only the chronic cases, the most important of which are those due to myelogenous leukemia, lymphatic leu-

kemia, Hodgkin's disease, chronic malaria, splenic anemia and Banti's disease, hemolytic jaundice, polycythemia vera, pernicious anemia, Gaucher's disease, von Jaksch's disease, syphilis (hereditary and acquired), tuberculosis, kala-azar, chronic infections, Still's disease, purpura, hepatic cirrhosis, obstruction to the portal vein, amyloid disease, and tumors.

The largest spleens usually occur in cases of myelogenous leukemia, Gaucher's disease, and kala-azar. The spleen may be almost as large in cases of splenic anemia or Banti's disease, and chronic malaria. In young children, from one to two years of age, the largest spleen is likely to occur in von Jaksch's disease. It varies in size, but usually is not so large in cases of hemolytic jaundice, polycythemia, syphilis, tuberculosis, Hodgkin's disease, Still's disease, lymphatic leukemia, chronic infections, and so forth. It may, however, become very large in cases of syphilis, tuberculosis, and Hodgkin's disease; in pernicious anemia, and in acute diseases it seldom is large.

Myelogenous leukemia.—The ordinary case of myelogenous leukemia may be easily recognized by the leukocyte count and enlarged spleen. Boothby of the Clinic is making a study of the basal metabolic rate and blood chemistry in such cases, which may be of some service in diagnosis. Thus far he has noted an increase in the basal metabolic rate and in the amino-acids of the blood. In cases in which the total leukocyte count is normal, the cases of so-called aleukemic leukemia, the differential count decides the diagnosis. Patients with a rare form of acute myelogenous leukemia are very ill, usually with a lower total leukocyte count, but many more immature cells. In certain cases in which the spleen is rather small and glands are somewhat enlarged, the diagnosis depends entirely on the differential count, but even so there may be many young cells that cannot be readily differentiated as belonging to the myelocytic or lymphocytic series.

Lymphatic leukemia.—In cases of lymphatic leukemia the lymph-glandular enlargement and continuously high leukocyte count, with 80 per cent or more of lymphocytes, are too well known to need repetition. Here also the total leukocyte count may not be increased, the diagnosis depending on the differential count. In certain cases the splenic enlargement may occur preceding the glandular enlargement, and thus lead to a diagnosis of mye-

*Read before the Minnesota State Medical Association, St. Paul, October, 1923.

logogenous leukemia, especially if the cells are young, or of some other form of splenomegaly if the total leukocyte count is not increased. A number of years ago I observed a case in which the splenic enlargement was the outstanding feature, and at first the total leukocyte count was about 9,000. The high percentage of lymphocytes (about 80 per cent) led to the correct diagnosis even before the glands became enlarged. Before death occurred three months later, the glands and the spleen were markedly enlarged and the leukocyte count was about 90,000. The value of careful study of the cells with regard to maturity should be emphasized, as in this way a good idea can be obtained of the activity of the process. In the acute type of lymphatic leukemia the total leukocyte count often is not greatly increased, and the spleen usually is not enlarged. The acute illness of the patient and the rapidly fatal course of the disease are outstanding features. On the whole, in cases of lymphatic leukemia, the splenic enlargement is not a prominent feature in the disease.

Occasionally a case is observed in which there is a combination of clinical and laboratory evidence of the lymphatic and myelogenous forms, the so-called mixed leukemia. There is likely to be both glandular and splenic enlargement with a moderately high lymphocyte percentage, but also a rather high myelocyte count. At least one case of lymphosarcoma, in my experience (Case A379656) revealed the blood changes of lymphatic leukemia. The spleen was very large; the leukocytes numbered 82,200, the lymphocytes were 92 per cent. After the application of radium, the spleen subsided greatly, and leukocytes numbered 6,900, but lymphocytes were 75.5 per cent. Before the patient died, distinct signs of pulmonary trouble appeared, which were thought to be due to leukemic infiltration of the lung. At necropsy definite lymphosarcoma of the spleen, lungs, liver, stomach, kidneys, intestines and lymph nodes, and a great many mitotic figures were found.

The rather uncommon cases of infectious lymphadenopathy and lymphocytosis should be mentioned here. Many or all lymph glands may be enlarged; the leukocyte count almost resembles that in cases of lymphatic leukemia, except that the lymphocyte percentage ordinarily is not so high. On careful scrutiny of the cells, however, they are seen to be mature lymphocytes, rather than varying numbers of younger forms, as is seen in cases of

leukemia. Such cases are extremely difficult to differentiate, and only time can make one absolutely sure of the diagnosis. Case A21154 was of this type. The glands in the neck were enlarged. Leukocytes were 22,600; lymphocytes 80.5 per cent. The patient's tonsils were removed and radium applied to the glands and spleen. Sixteen months later the glands had almost entirely subsided; the leukocytes were 10,500 and the lymphocytes 40.5 per cent. The patient is in excellent health three years after the onset.

Hodgkin's disease.—The spleen is usually not greatly enlarged in cases of Hodgkin's disease. The symptoms are well known, but attention should be directed to the itching that occurs in many of these cases. I often find it necessary to excise one of the easily accessible glands for microscopic examination to clinch the diagnosis. In the so-called splenic Hodgkin's disease in which there may be little or no glandular involvement, diagnosis is difficult. The condition may be mistaken for another type of splenomegaly until operation or necropsy reveals the correct condition. Occasionally lymphosarcoma may present the clinical picture of Hodgkin's disease, and microscopic examination will reveal the condition.

Chronic malaria.—In some cases of chronic malaria, the spleen, as is well known, is large and hard, the so-called ague cake. Held asserts that the organism may be more readily discovered by examining the blood forty-eight hours after the subcutaneous injection of 1 c.c. of 1:1000 solution of epinephrin to force the organisms out of the spleen. Certain of the more serious splenomegalies should not be confused with this disease, as so often occurs. We do not often find, in this part of the country, a very large spleen attributable to malaria.

There is a small group of cases presenting the other evidences of splenic anemia, in which there is a history of malaria, or of the patient's residence in a malarious district. The blood findings in these cases may not be distinguishable from those in cases of splenic anemia. I do not recall, however, any case of this kind in which the organisms were recovered from the blood, and therefore the diagnosis of malarial splenomegaly with secondary anemia is somewhat conjectural.

Splenic anemia and Banti's disease.—The diagnosis of splenic anemia depends on the existence of splenomegaly, varying degrees of anemia of the secondary type, usually leukopenia and relative

lymphocytosis, and the frequent occurrence of gastric and intestinal hemorrhages. Because of the hemorrhages, the condition is often diagnosed gastric or duodenal ulcer, the splenic enlargement, even though considerable, being overlooked or disregarded. It should be emphasized that, in cases of gastric or intestinal hemorrhage, splenic anemia must be eliminated as a cause. In the later stage of the disease (Banti's disease) the existence of a very large spleen and ascites due to the associated hepatic cirrhosis, together with the foregoing findings, usually suffice to make the diagnosis. Sometimes it will be impossible to separate the condition from primary hepatic cirrhosis with splenomegaly. The existence of a large liver and a comparatively small spleen or an atrophic liver with rather a small spleen, especially if ascites is present, favors a diagnosis of hepatic cirrhosis. Occasionally syphilis presents such a picture, as occurred in a case in the Clinic recently (Case A415425). Norris, Symmers, and Shapiro believe that all cases of so-called Banti's disease are due to syphilis. The importance of diagnosis in this disease is even greater than its difficulties, since splenectomy in early cases leads to marked improvement or cure.

Hemolytic jaundice.—This condition may be either congenital or acquired. Its chief characteristics are splenic enlargement, usually moderate, an icteric tinge of the skin and sclerae, the absence of bile in the urine and its presence in the stool. Several members of the same family may be affected. The red cells are much more fragile than normal, as shown by the fragility test in which their resistance to hypotonic salt solution is determined (Ribierre). Schneider's test of the urobilin and urobilinogen content of the bile obtained from the duodenum by a Rehfuß tube is of much value. This test shows a practically constant increase of urobilin and the appearance of urobilinogen, running as high as 10,000 units of the combined pigments, whereas 1,000 units is fixed by Schneider as the upper normal. This increase of urobilin and the appearance of urobilinogen in the bile, is probably the result of increased blood destruction, and the consequent conversion of the liberated hemoglobin into an increased amount of bile pigment. However, the rôle of hemoglobin in the formation of bile pigment is not settled. The appearance of these two pigments and the absence of the normal bile pigments in the urine are of value in the diagnosis. The tests for the fragility of erythrocytes

and for abnormal bile pigments are the strongest links in the diagnostic chain of this disease. The number of reticulated cells may also be important, since they reach their highest numbers in this disease, that is, 10 to 20 per cent.

The frequency of gallstone attacks in cases of hemolytic jaundice must be taken into consideration since the jaundice is often attributed to such attacks. In Giffin's series of cases, 58 per cent were associated with gallstones. Needless to say, such jaundice is not relieved by cholecystectomy, but usually completely disappears after splenectomy. Certain of these cases resemble cases of pernicious anemia, but in pernicious anemia the fragility of the red cells is decreased while in hemolytic jaundice it is increased. Usually the spleen in pernicious anemia is not so large, the percentage of reticulated red cells is much smaller, and the urobilin and the urobilinogen values in the duodenal contents are not so high. The apparent good health of the patient with hemolytic jaundice contrasts markedly with his weakness when he has pernicious anemia, but occasionally a patient with hemolytic jaundice may be very anemic and weak. Even the hemoglobin indexes of the two conditions may be similar, but with hemolytic jaundice the color index is usually below 1, averaging 0.8. Occasionally a strongly positive Wassermann reaction is obtained in a case in which syphilis is not otherwise demonstrable. It may be difficult to make a diagnosis in a few cases in which biliary cirrhosis and hemolytic jaundice appear to be combined.

Polycythemia vera.—In polycythemia vera, or Vaquez-Osler's disease, the outstanding features, clinically, are the intense bluish-red or intense red of the skin, especially of the face, and mucous membranes, particularly of the lips and tongue; certain patients appear almost cyanotic. They often have headache and sometimes high blood pressure. The spleen varies greatly in size, and occasionally it is not palpable. It never reaches the enormous size seen in cases of myelogenous leukemia, or Gaucher's disease. The most important laboratory finding is the increased number of erythrocytes, varying from 5,500,000 to 10,000,000, or, as in a case observed in the Mayo Clinic, to 14,000,000. The hemoglobin, by the acid hematin method of estimation, is increased; the readings by the Dare method, however, are often very inaccurate. The blood viscosity is practically always increased, as is the total blood volume, in some

cases being more than twice the normal. Naturally, the cell percentage of the total blood volume is increased sometimes much above the normal of 43 to 45 per cent. In a recent test one patient (Case A405531) had 224 c.c. of blood for each kilogram of body weight, whereas 90 to 95 c.c. is normal. All but 67 c.c. of this was cells. The highest erythrocyte count was 7,080,000, and the acid hematin estimation of hemoglobin was 174 per cent. The viscosity was greatly increased; 1:15 and 1:14.2, at two readings, as compared with the normal of 1:4.5. The leukocyte count in this case was high, at one time 39,800. The principal complaint was weakness, and swelling of the feet. The skin and mucous membranes were an intense bluish-red; the eyes were bloodshot. On account of the increased viscosity, such patients are likely to develop thrombosis, as this man did from puncture of the vein. He died about three years after the onset of the disease.

Brown and Giffin have made some interesting observations on the blood capillaries in cases of polycythemia vera. They found that in many capillary loops the arterial portion is not dilated, but that the venous side of the loop is usually markedly dilated. Polycythemia may be overlooked and diagnosed as a neurotic complaint, unless a careful blood count and hemoglobin estimation are made on all patients with unusually red or bluish-red facies and mucous membranes. In cases of polycythemia of congenital heart disease, the cell and hemoglobin values may also be high, but increased total blood volume may be lacking and the murmurs and other signs of congenital heart disease present. The spleen is seldom enlarged. One recent case, observed at the Clinic, presented the laboratory evidence of polycythemia vera, with the physical findings of congenital heart disease. In certain cases there is a resemblance to polycythemia in the facies, but laboratory evidence and the enlarged spleen are lacking. This condition appears to be capillary hypertrophy.

Pernicious anemia.—In cases of pernicious anemia, splenomegaly is not constant, and is seldom marked. It is distinguished by the almost characteristic blood picture, sore tongue, achlorhydria, paresthesias and other nerve phenomena, and extreme weakness, ordinarily without much loss of flesh. The usual blood picture of low hemoglobin and erythrocyte count, high hemoglobin index, marked irregularity in shape and size of red

cells, and the frequent presence of megaloblasts, is too well known to need repetition. Sufficient attention often is not paid to the soreness of the tongue, and its atrophic appearance, the achlorhydria and the neurologic symptoms and signs, and too much is expected of the blood count. By carefully considering these features, diagnosis may often be made long before the blood picture becomes characteristic. Here again the Schneider test of the amount of urobilin and urobilinogen in the material obtained by duodenal tubing, and the examination of the fresh urine for the same pigments may be important, and second only to the findings in hemolytic jaundice, the average in the duodenal contents being about 3,000 units. Individual cases will vary from time to time. The reticulated erythrocytes are likely to be increased to between 2 and 5 per cent. The low leukocyte count and relative lymphocytosis may also aid in the diagnosis; a low platelet count is the rule. Occasionally a case is observed in which the blood picture is that of pernicious anemia, with free hydrochloric acid in the gastric contents, the spleen usually more or less enlarged and neurologic findings absent. This may or may not be another type.

Acute aplastic anemia is often confused with pernicious anemia, and is sometimes classified with it. The rapidly fatal course, absence of glossitis and neurologic symptoms, persistent very low leukocyte count, low platelet count, absence of nucleated erythrocytes, absent or much reduced reticulated cells, and the lack of increase of urobilin and urobilinogen in the duodenal contents and their absence in the urine, serve to differentiate it. The findings correspond to the lesion, namely, a rapidly progressing fatty change of the bone-marrow.

Sprue may be confused with pernicious anemia on account of the sore tongue, diarrhea, achylia and anemia, but may ordinarily be eliminated by examination of the duodenal contents and urine for abnormal bile pigments, neurologic examination, reticulated cell count, and the recovery of the specific monilia psilosis of sprue in the stool.

Pellagra may be confusing because of the sore mouth, tongue, diarrhea and achylia, but also distinguishable by the foregoing laboratory tests, and the characteristic skin changes. The exact relationship of pernicious anemia, sprue, and pellagra is not clear. A patient with pernicious anemia may not be anemic when he appears for examina-

tion, and even though very anemic may be only pale and not the usual greenish yellow.

Gaucher's disease.—This condition is not often encountered. Previous to 1920 there were only twenty-four cases reported in the literature; it is probable, however, that many cases have been overlooked or not reported. The spleen in Gaucher's disease may be as large as in myelogenous leukemia. The conjunctival and microscopic findings are characteristic.

Von Jaksch's disease.—The enlarged spleen in these cases is usually found in children from one to two years of age; it is generally accompanied by rickets, and sometimes by hereditary syphilis. It has no characteristic blood picture, but the large spleen, the age of the patient, and the rickets, usually identify the condition.

Syphilitic spleen.—The enlarged spleen of syphilis presents nothing characteristic in itself and is differentiated by the presence of the positive Wassermann reaction, a history of acquired or hereditary syphilis, and physical evidences of this disease. In a case observed in the Mayo Clinic recently there were symptoms and signs, including gastric hemorrhages, of Banti's disease. Every case of splenomegaly should be investigated for syphilis. The positive Wassermann reaction occasionally obtained in cases of hemolytic icterus and of pernicious anemia does not necessarily indicate syphilis.

Tuberculous spleen.—This condition can only be suspected, but it may occur either as a so-called primary condition, in which case the spleen may be large, or it may occur as a phase of miliary tuberculosis. Tuberculosis elsewhere in the body should not lead to the hasty diagnosis of tuberculous spleen. The condition may even be associated with anemia, resembling pernicious anemia, as was pointed out by Giffin. Its presence should always be suspected in any case in which splenomegaly is not otherwise definitely accounted for. The history of former ascites should excite suspicion.

Kala-azar.—The splenomegaly of kala-azar or Leishmaniasis need not be considered in the diagnosis of splenomegaly unless the patients reside in, or come from districts in India, Africa or Sicily. The diagnosis is made by finding characteristic Leishman-Donovan bodies in the material obtained by splenic puncture.

Chronic infectious splenomegaly.—Many cases of splenomegaly seem to be due to chronic septic

infection in various areas in the body, especially the tonsils and teeth, and associated with furunculosis, phlebitis, arthritis, nephritis, and so forth. The diagnosis can be made only by finding infection elsewhere, and excluding other causes. The spleen, in such cases, usually is not large, but it may be enormous.

Still's disease.—The splenomegaly occurring in Still's disease probably belongs to the chronic infectious group. It is a rheumatoid arthritis, usually occurring in childhood and youth, accompanied by splenomegaly; and glandular enlargement.

Purpura.—The splenomegaly occurring in purpura may be classified with the chronic septic infections. The spleen is a menacing factor in the disease, since, as has been recently shown by Brill and Rosenthal, its removal leads to a symptomatic cure. In one case in the Clinic (Case A413241) hemorrhage from the uterus, uncontrollable by any other means, was entirely cured, and the patient restored to apparent health by splenectomy. In such cases the diagnostic features are purpuric spots, positive tourniquet test, low platelet count, markedly prolonged bleeding time, but usually normal coagulation time of the venous blood. The tourniquet test consists in applying the arm band of the blood-pressure instrument at a pressure impeding the venous return, but not preventing the entrance of blood, usually about 100 mm. for three to five minutes. If the test is positive, small petechiae will appear on the skin of the arm.

Hepatic cirrhosis.—Certain of these cases with splenomegaly and ascites do not correspond to the Banti type of splenic anemia, and are diagnosed by the absence of the suggestive blood findings and the occurrence of jaundice. Occasionally, in cases of portal cirrhosis, the spleen is enlarged. The diagnosis depends principally on the enlarged liver, and jaundice without ascites.

Obstruction to the portal vein.—Splenomegaly due to portal obstruction may be suspected when sufficient cause exists, such as carcinoma of the stomach, pancreas or gallbladder, and Hodgkin's disease. Ascites will usually be present; jaundice may occur because of the pressure on the hepatic ducts. The obstruction may also be due to recurrent abdominal phlebitis, and portal thrombosis.

The splenomegalies of less frequent occurrence, such as are due to amyloid disease, tumors, cysts, hemorrhage, injury or twisted pedicle and the acute splenomegalies, will not be discussed here.

GENERAL DISCUSSION

Schneider's test of the urobilin and urobilinogen values of the duodenal contents has thus far been of diagnostic value only in the anemias associated with hemolysis, notably pernicious anemia and hemolytic icterus, increased values occurring constantly in the latter and in about 85 per cent of cases of the former. The total combined values are normally not more than 1,000 units, and the appearance of urobilinogen is abnormal. The presence of urobilin and urobilinogen in the freshly voided urine has the same significance as their excess in the duodenal contents. Care must be taken to test the fresh urine, since on standing, urobilinogen is quickly converted into urobilin. The fragility test is of value only in distinguishing hemolytic jaundice from other conditions. In the normal control, hemolysis usually begins in about 0.42 per cent sodium chlorid solution, and is complete in about 0.32 per cent, while in hemolytic icterus it may begin even as high as 0.6 per cent and be complete at 0.46 per cent; but the average is 0.52 per cent for beginning hemolysis and 0.4 per cent for complete hemolysis. The viscosity of the blood is considerably increased in a number of diseases, but in diagnosing splenic conditions its use is confined to differentiating cases of polycythemia vera; it is practically always increased in this disease. Its normal is about 1:4.5. The blood-volume and cell-volume estimations in the diagnosis of splenic conditions are of value practically only in cases of polycythemia vera. The normal is about 90 to 95 c.c. of blood for each kilogram of body weight, while 43 to 45 per cent of this is cells. Both or either of these may be variably increased in polycythemia vera. The study of the capillaries seems to be of value in distinguishing polycythemia vera from conditions resembling it. A count of the reticulated cells is important principally in determining the degree of blood regeneration, and of practical importance in the diagnosis of hemolytic icterus, in which the values may be 10 to 20 per cent, and in pernicious anemia with values usually of 2 to 5 per cent as against the average normal of 0.3 per cent and normal limits of 0.1 to 1 per cent.

DISCUSSION

DR. EDWARD L. TUOHY: This very able survey of the spleen is deserving the closest analysis and study. There are only two or three features I would care to emphasize. The one has to do with an observation of a patient that I reported some two or three years ago after a similar report had been made by the Chairman of this Section, Dr. Giffin. These were cases of extreme chronic increases in *normal leukocytes*, so-called "hyper-leukocytosis." At that time I reviewed the literature, and was impressed with the apparent fact that wherever we have hyper-function of the bone marrow the spleen enlarges. That point is deserving of consideration.

Another feature I wish to call your attention to comes to mind because of a remark made by Dr. John Rose Bradford (the man whose name is so identified with the condition of Massive Collapse of the Lung) while giving a clinic in London a year ago. He asked a group of doctors if any of them had ever seen a case of spleno-myelogenous leukemia in its inception, and apparently no one had seen one. In other words, most of them come to the doctor when the spleen is large. I kept that in mind and on my return had it called to my attention by one of my confreres that a patient we had seen on account of discomfort in the upper left quadrant,—a rather indefinite portion of the human anatomy in any case,—returned a year later with a full fledged picture of spleno-myelogenous leukemia, and unquestionably we had not recognized it in the beginning.

I was treating a patient for a very manifest syphilis and

she returned and casually complained of pain in the upper left quadrant. We made blood counts and found that our patient had spleno-myelogenous leukemia with a rather mild increase in blood count. The spleen could just be felt. Under intensive roentgenotherapy and the continuance of the treatment for syphilis that patient has remained in *statu quo* for just about two years. The leukocyte count has never come down to normal and the abnormal relationship of leukocyte still obtains. So I think I can safely answer Sir John Rose Bradford's question and state that I "have seen a case of spleno-myelogenous leukemia in its inception." I saw one previously but I did not know it.

The other feature I wish to call your attention to is that there have been a number of cases in the literature having to do with abdominal injury, followed by damage to the splenic vein, resulting in enlargement or combined with it a condition of gastric hemorrhage as mentioned by Dr. Conner. That must not be forgotten in determining the cause of unusual splenomegaly. The damage to the vein produces enough trouble to lead to thrombus, which in turn is followed by varices in collateral vessels. The spleen is a most interesting organ and it is entirely wholesome to take this broad view of it and make the analysis as given by the essayist.

DR. J. P. SCHNEIDER: I think the doctor is to be congratulated on covering the field so thoroughly. I merely want to touch upon a few points that occur to me. A principle that it is well always to bear in mind is that of the influence of age. Regardless of the pathology causing splenic enlargement, the younger the patient the larger will the spleen become. Hence, ordinary Laennec's Cirrhosis in children will frequently present a relatively very large spleen and often lead to an erroneous diagnosis of Banti's disease.

I was misled by a negro patient, who had a very long-pediced fibroid in the left hypochondrium and which was mistaken for an enlarged spleen. Particularly in the negro race, fibroid disease of the uterus may give rise to pedunculated fibroids. One further condition that sometimes is mistaken for a primary splenomegaly is a non-hemolytic streptococcal endocarditis with an enlargement of the spleen. I have seen a three hundred per cent en-

larged spleen as the result of infarction in this condition. Very frequently the endocarditis will be overlooked.

DR. H. T. HELMHOLZ: I have been very much interested in this paper because of the unusual number of enlargements of the spleen that we have seen in Rochester in children, and one in particular that I should like to recount in view of what Dr. Tuohy just said. A boy of about nine years of age, three years before, had received a 22 revolver shot in the right chest, the bullet lodging opposite the first lumbar vertebra. The child made a perfect recovery and as far as his father knew was perfectly well. He was brought to us and we found an enormous spleen. The spleen extended beyond the midline to the right and to the anterior superior spine on the left and midway between the umbilicus and the symphysis in the midline. Practically every one of the factors that Dr. Conner has brought up could be excluded by examination and the possibility of an injury to the splenic vessels having occurred suggested itself. We thought that that possibly might have been the cause. The spleen was removed and the splenic vessels were found to be intact but there were thrombi throughout the entire spleen.

DR. H. Z. GIFFIN: If as Chairman I may be allowed to say a word, I should like to call attention to two groups of polycythemics in which diagnosis is frequently difficult. The first is the polycythemic with pallor, and the second, one who has become anemic from loss of blood. In these two groups, an accurate history, estimations of the total blood volume and of the red cell volume, and the testing of the viscosity of the blood are most important. The polycythemic who has become anemic from loss of blood may quite easily be mistaken for a case of splenic anemia.

The recent success of splenectomy in severe cases of purpura hemorrhagica is known to all of us, and there seems to be no question that remarkable results have been obtained. It will be a difficult matter to know just when to advise splenectomy. Frequent transfusions are curative in certain mild types of purpura hemorrhagica, but on the other hand, one cannot predict that the case will not prove to be a severe or even a fatal one. The differential diagnosis between purpura hemorrhagica, hemophilia and aplastic anemia is especially important in this connection.

THE ANTINARCOTIC LAW AND CODEIN

A committee appointed by the Ohio State Medical Association to study the habit-forming properties of codein, with a view to determining the need for changing existing law, has submitted to the Council of that Association certain data collected by the committee. A questionnaire was sent to 100 general practitioners and to 125 physicians engaged in special branches of practice.

Of the fifty-seven general practitioners who replied, forty-eight did not regard codein as a habit-forming drug, and nine were unable to express an opinion. Seven reported that in cases of codein addiction the habit was easily broken. Ten regarded it as inconsistent with public interest to exempt codein sulphate from the operation of the Harrison Narcotic Law, thirty-nine wrote that it might be so exempted, and eight were of the opinion while it might be exempted, yet it should in its sale be limited to sales on physicians' prescriptions.

Fifty-eight physicians practicing special branches of med-

icine replied. Of these forty-nine did not regard codein sulphate as a habit-forming drug, six thought that it would tend to form a habit, and three were unwilling to express an opinion. Eight reported that the codein habit was easily broken, but two were of a contrary opinion. To the inquiry as to whether it is consistent with public interest to exempt codein from the operation of the Harrison Narcotic Law, twelve replied in the negative and thirty-nine in the affirmative. Three, however, would have codein dispensed only on physicians' prescriptions.

In the answers to these questionnaires it was suggested that the infrequency with which codein addicts now appear might be attributable not to the fact that it does not possess habit-forming properties, but to the fact that it is as easy to get heroin, morphin and cocain as it is to get codein, and that if any change were made in the law that would make it easier to obtain codein than to obtain the other drugs, codein addiction might become more common.—A. M. A. Bulletin, Nov., 1923.

RETROPERITONEAL TUMOR*

S. H. BAXTER, M.D., F.A.C.S.

Minneapolis

There are many organs and tissues occupying the retroperitoneal space, each of which is subject to a variety of tumors. The kidney, suprarenal glands, pancreas, parts of the bowel, the mesentery, etc., may each be the site of development of new growth and therefore of a retroperitoneal tumor and, broadly speaking, the title of the present discussion would include all these growths. This, however, would make the term include such numerous and widely diversified tumors that for practical convenience it is commonly applied to the primary tumors arising from the connective tissue of the retroperitoneal space, either lipomas or sarcomas in their various combinations and modifications. Even in this narrowed sense a comprehensive review of the literature and of all the surgical bearings of the condition would require a much more extended discussion than is permissible for the present occasion.

To bring the subject concretely before the society two cases are reported.

CASE 1. Female, aged 42. Well as a child, menses regular and normal. Has one child aged 5 years, instrumental delivery. Tonsillectomy 1920.

Present complaint: Pain in right hip; unable to walk on account of pain.

History: Had attack of pain in hip in 1918—duration one week, followed by complete relief until January, 1919. Then, without apparent cause, began again to have pain in right hip. Pain was worse when walking. In April, 1919, she noticed a small mass just above the right sacro-iliac joint; it was not painful, but there was a very tender point just below the mass. The tumor slowly increased in size. There is no edema of the right lower limb, but it feels as though asleep at times, and seems colder than the left. Patient has occasional headache. No history of urinary disturbance. No nausea or vomiting. Bowels constipated. The pain is more severe at night and is occasionally transmitted to the knee.

Examination: A tumor is palpable in the right gluteal muscle half the size of the palm of the hand; tense, not tender to touch. Vaginal examination reveals a solid immovable tumor the size of a lemon to the right of the uterus over the sacro-iliac region.

Operation Nov. 14, 1920: Exploratory incision over tumor in right gluteal region. On going through the deep fascia and into the muscle an encapsulated soft tumor of the consistency and appearance of thyroid tissue was encountered. There were several prolongations of the tumor

which could be readily shelled out except at the base where they sprang from the vicinity of the sacro-sciatic notch. These masses were removed as far as possible and 50 mgm. of radium was placed against the base of the tumor. Pathological diagnosis—fibro-myxo-sarcoma of very low grade malignancy.

Operation Dec. 10, 1920, on diagnosis of retroperitoneal sarcoma in the right pelvis. Median abdominal incision. A tumor was found behind the peritoneum in the true pelvis, extending downward about 3 inches from the iliopectineal line. The posterior parietal peritoneum was incised at the inner side of the internal iliac artery. The ureter and iliac vessels could be seen lying on the surface of the tumor. The tumor was encapsulated and was enucleated without difficulty. At the sacro-sciatic notch it passed out of the pelvis and from this point its extension followed intermuscular planes in the gluteal region. The bone at the sacro-sciatic notch was softened by pressure of the tumor. The patient is still living, but she has had a great deal of pain and a discharging sinus, and a recent report indicates that her condition is unsatisfactory.

CASE 2.—Female, aged 45. Had a miscarriage fourteen years ago, menses irregular. One child living and well, aged 11. Bowels somewhat constipated. No history of previous serious illness. About eighteen months ago she first noticed a swelling in the right abdomen accompanied by a sensation of weight and a "beating sensation." She had no pain in the abdomen, but the fact that there was something present in her side made her very nervous. There were no symptoms of bladder or kidney trouble. Has backache and pain through shoulders and up into her neck. Has smothering sensation when lying down. During the past three months the tumor has grown rapidly and the pain in the back and shoulders has been more severe. She consulted a surgeon several months ago who made a diagnosis of tumor of right kidney and advised an operation.

Examination reveals an extensive nodular, solid, but not hard, tumor occupying the entire lower abdomen, making it about the size of an eight months pregnancy. There is some fluctuation in the lower abdomen when the patient stands—probably free peritoneal fluid. There is dullness on percussion over the entire abdomen except in left flank and over the stomach. The course of the colon cannot be followed. Vaginal examination is inconclusive; the pelvic organs cannot be identified. The tumor was thought to be a multi-locular ovarian cyst.

Operation Jan. 16, 1923: On opening the abdomen an enormous tumor entirely filling the abdominal cavity was encountered. Abdominal viscera were nowhere in sight. The peritoneum covering the tumor was a very thin vascular veil loosely connected to the underlying layer which proved to be the capsule of the tumor and which contained numerous large blood vessels. The uterus, tubes and ovaries were normal. The cecum and ascending colon could not be seen. What appeared to be descending colon was closely attached to the left side of the tumor but could be easily separated from it. The left kidney felt normal. The right kidney was behind the tumor and could not be identified. The transverse colon was attached along the upper border of the tumor. Small bowel was not seen and

*Presented before the Minneapolis Surgical Society, Minneapolis, November, 1923.

the mesentery could not be identified. The capsule of the tumor was incised and a line of cleavage found between the tumor and its capsule, but in attempting to follow this line free venous bleeding resulted. Exploration for two inches into the substance of the tumor revealed, so far as we went, a pure lipoma. The anatomical relationships are reported as they appeared and were interpreted at the operation, but the true condition will be revealed by the necropsy report. The removal of the tumor was regarded as involving insurmountable difficulties and risks and was not attempted. A few weeks later two tumors appeared in the pericranium. One of these was removed, and microscopical examination showed it to be a spindle-cell sarcoma growing rapidly. Ptosis of one eyelid developed, and physical signs of involvement of the pleurae. Death occurred about eighteen months after patient first noticed the tumor.

Autopsy is limited to the abdomen. The subcutaneous fat is very scant. Presenting in the incision is a large yellowish tumor. It is apparently everywhere covered with peritoneum except on the posterior surface. The tumor fills the right flank, is in contact with the inferior surface of the liver and below with the brim of the pelvis. It extends across the mid-line and has pushed the cecum and ascending colon over into the left flank. Attempt to strip the peritoneum from the tumor is only partially successful for in some areas it cannot be separated. The small bowel has all been crowded far into the left abdomen and is entirely covered until the tumor is raised out of the abdomen.

When removed the tumor weighed 5,075 gm. including the right kidney. It shows a deep depression corresponding to the spinal column. The right kidney has been carried to the left of the spinal column and rotated on its long axis, so that the pelvis of the kidney looks toward the right side. It is almost completely imbedded in the tumor and the ureter lies within the tumor almost down to the brim of the pelvis. The kidney has not been invaded by the tumor, and its capsule can be readily stripped off. The right adrenal lies on the posterior surface of the tumor. The left kidney is apparently normal. There is moderate dilatation of both kidney pelves and of both ureters. The spleen shows no gross lesion. The liver is about normal in size but there is a deep depression in the right lobe due to pressure atrophy. There are no tumors in the liver. There are numerous hard nodules scattered over the parietal and visceral pleurae of both sides of the chest. These nodules extend for only a short distance into the parenchyma of the lung. In the posterior mediastinum is a tumor about 5 cm. in diameter which bulges into both pleural cavities. The abdominal tumor had not dissected between the leaves of the mesentery of the small bowel, but the transverse mesocolon had disappeared and the colon throughout lay in close contact with the tumor. The aorta and vena cava lay behind the tumor but closely covered by it, and the mesenteric arteries passed for a considerable distance through the tumor and between its lobules. There is no edema of the lower extremities. The tumor mass is lobulated. On section it has a variegated appearance. In some parts there are masses 4 to 5 cm. in diameter which are apparently normal adipose tissue.

In other parts there are firm grayish-white translucent masses. Other similar areas have a yellowish color. In the center of the tumor is a large mass of necrotic tissue. Microscopically various parts of the tumor show various histological structure. In some areas it is composed of normal adult adipose tissue, in some of fatty tissue of embryonal type. Some parts of it show the structure of spindle cell sarcoma, some of fibro-sarcoma, and in others the structure is that of a myxoma.

The occurrence of two cases within three years in a comparatively small surgical practice indicates that the condition is not so rare as it is commonly supposed to be. On the other hand it is sufficiently infrequent to justify calling attention to this coincidence as an example of a fact often observed that one unusual case is often followed in a short time by another one of similar nature. These two cases are reported not with the hope of presenting any new facts, but of reiterating some that are old, and of calling attention to a condition which is apt to be overlooked. Moreover, a study and comparison of the writings upon this subject, instead of clarifying it, in some respects make it more obscure, and it is almost impossible to compare the statistics and collected cases of various authors, because no two use the same classification and in a collection of reports of cases of retroperitoneal lipomas will be found a considerable proportion of myxomas and sarcomas. The title of this report was therefore chosen advisedly, for it is a question whether even the so-called pure lipomas, in view of their behavior and their pathological relationships, should not be put into a different class from lipomas in other regions of the body; until their exact status is determined, the term retroperitoneal tumor will be sufficiently explicit, for, for practical purposes, it may be usually considered as synonymous with retroperitoneal sarcoma. The literature on this condition is comparatively recent, but is quite extensive considering the small number of cases reported. Virchow, although he mentions the form of fatty hyperplasia which is frequently seen around the kidney in cases of hydronephrosis, renal calculus and other chronic forms of renal disturbance, makes no mention of the definite fatty tumors which are occasionally found in that region. Adami in 1896 was unable to find any general article on the subject of retroperitoneal lipoma in the English language, and after an exhaustive study of the literature was able to collect reports of only 40 cases, to which he added two of his own. Wahlfendorf¹ in 1921 collected reports of 165 cases

of lipoma and reports on Adami's cases are included in this series. The latest case report is by Greensfelder and Bettman.² On the subject of retroperitoneal sarcoma the articles by Steele³ in 1900 and 1904 are classical. He collected a total of 96 cases. In April, 1923, Andrews⁴ collected the cases in the literature since Steele's report and added 28 cases from the Mayo Clinic, making a total of 142 cases. The two cases reported herewith bring the number of retroperitoneal sarcoma reported up to 144. At this point attention is again drawn to the uncertain classification of these growths. The articles by Adami and Wahleldorf are under the titles of Retroperitoneal Lipoma. In one of the two original cases reported by Adami he found that "in one region * * * an oat-shaped cell growth replaced well formed connective tissue, so that sections from this area presented a markedly sarcomatous appearance"; and in the other "the tumor was found to consist largely of adipose tissue in a voluminous stroma of embryonic connective tissue with abundant nuclei between the fat cells." Of 151 cases tabulated as retroperitoneal lipoma by Wahleldorf, 82 were classified as mixed tumors, 20 presented sarcomatous changes and in 15 there were recurrences after operation, indicating strong tendency toward malignancy in these tumors. It is probable that these published statistics do not correctly indicate the true number of retroperitoneal tumors, and a remark by Hertzler may be à propos: "Few men take any great pleasure in reporting a case in which the diagnosis was wrong and the treatment a failure."

The etiology of these tumors is unknown; hence there has been a great deal of speculation and many theories have been advanced to explain them. The occurrence of lipoma is not related to general corpulency, but on the contrary many of its victims are below average weight and the tumor even when it is apparently a pure lipoma seems to grow at the expense of the normal fatty tissue of the individual. Pregnancy has been regarded as an explanation of the greater frequency of lipomas in women than in men, but no acceptable explanation is given as to how it operates. Mechanical irritation has been suggested, due to the movements of the hollow organs and the pulling on the tissues by their alternate filling and emptying. Nutritional conditions, abuse of alcohol with rapid increase in body weight seem to be a factor in some cases.

The lymph glands are undoubtedly the point of origin in many retroperitoneal sarcomas, and Askanazy regarded it as possible that lipoma might also spring from them through some process of fatty degeneration. Inflammatory processes are a factor in some cases. Kornmann found inflammatory changes in kidneys, spleen and liver and concluded that the condition in some cases at least is not a tumor of pure type but is related to inflammatory processes in other organs as well. Finally these tumors, both lipoma and sarcoma, may arise as tumors of the embryonic mesenchymal layer, and this seems to be the most plausible explanation of their presence.

Retroperitoneal tumor is more frequent in women than in men, 72 per cent of patients in Wahleldorf's collected cases of lipomata being women. Among the cases reported as sarcoma, however, the incidence in the two sexes is about the same. A few cases have been reported in children and in one instance a child of one year had a tumor of the pararenal fat that was of prenatal origin. Nearly 90 per cent of Wahleldorf's cases occurred between ages of twenty and sixty. The origin of the tumor is in the abdomen in about 80 per cent; in the pelvis in 20 per cent. Of the abdominal tumors, 72 per cent are lateral; 28 per cent median. They originated from the kidney capsule in 23 per cent; from the pararenal and lumbar fat in 35 per cent, and from the mesentery in 20 per cent. Among the occasional sites in which tumors have been reported may be mentioned the gastro-hepatic omentum, in which Peyrot found a lipoma undergoing myxomatous and sarcomatous changes. Alsborg described a tumor of the transverse mesocolon. Two cases have been reported of tumor of the mesentery of the small bowel; a few cases of lipoma of the broad ligament. Chiari reported one case of symmetrical lipomas developing beneath both ureters. The pathology of these tumors is confused by the fact that they originate in a region where there is a great variety of structures and which is also a frequent site for teratoma.

In tumors classified as lipomas are frequently found areas of myxoid tissue, which is a primitive tissue closely related to and often associated with sarcoma. Even tumors which are apparently pure lipomas frequently recur after surgical removal and thus suggest a tendency to malignancy and raise the doubt whether they are in fact pure lipomas or should not rather be classified as mixed

tumors. The same observation applies also to the other connective tissue tumors of this region, which are seldom of pure type. It is, indeed, a well recognized fact that any one of the group of connective tissue tumors may show areas undergoing conversion into other members of the group. The reported cases show that in these large tumors we may have examples of practically every form of connective tissue from fibrous to adipose and in all possible combinations and admixtures with myxoid, cartilaginous and even bony tissue and that they have a strong tendency to reversion to embryonal type. Hertzler, indeed, favors the view that these tumors, even the pure lipomas, are to be regarded as embryonal in origin and not merely a reversion of an adult tissue to the embryonal type. This view is supported by the fact that in some cases the tumor is known to have begun in childhood and by the further fact that the most frequent location in all the cases reported is the region of the kidney, which is a frequent site for teratoma and tumors of embryonal origin.

From a practical standpoint, it is important to emphasize the fact that all these tumors exhibit malignancy in one way or another, either by reason of their inherent nature or on account of their widespread extensions around important structures, which extensions are ultimately fatal if permitted to remain and at the same time in many cases cannot be successfully removed by operation. The pure lipomas in this region, therefore, should be regarded differently than we regard tumors of the same structure in other localities. The name lipoma arouses in the mind of the surgeon a feeling of confidence and of mastery of the situation which is likely to be severely shaken when he encounters a lipoma of the retroperitoneal space.

Symptoms are remarkable for their absence until the tumor has reached large size. Pain is very infrequent. There is usually no disturbance of the gastro-intestinal or urinary functions. The most remarkable effect of the tumor is loss of weight of the patient. The tumor seems to develop at the expense of the patient's fat and there is usually great emaciation, but without the characteristic appearance of cachexia. When the tumor has become very large symptoms attributable to pressure will develop, such as constipation, interference with respiration, disturbance of urinary function, edema of legs, scrotum or vulva, and ascites.

The correct diagnosis is seldom made before

operation. It seems probable that Greensfelder² has pointed out the explanation for this failure in many instances to recognize the character of the tumor. He says in reporting a case, "We confess that the condition of retroperitoneal lipoma did not enter our minds." Encouraged by his example, the present writer is constrained to make the same confession. On account of the soft consistency of the tumor which gives a sensation as of fluctuation, the diagnosis of ovarian cyst has been made most frequently. The emaciation without cachexia produced, in the second case in this report, a very good example of the facies ovariana. The error in that case could have been avoided by closer attention to the history and by x-ray examination of the ureters, kidneys and colon. These would have shown the dislocations of the right kidney and ureter and of the ascending and transverse colon, producing distorted relationships which could have been caused only by a growth behind the peritoneum and not by any possibility by a tumor within the peritoneal cavity. Of prime importance in the diagnosis is the relationship of the hollow viscera, and especially of the large bowel, to the tumor. The transverse colon crosses the summit of the tumor and the ascending or descending colon, depending on the side on which the tumor originates, is displaced toward the median line or the opposite side. This relationship when demonstrated will exclude tumors of the ovary, uterus, omentum, liver and spleen. A mesenteric cyst is at first lateral, then, becoming larger, is central and points toward the umbilicus. It is freely movable, especially transversely, and rotates upon its axis. It is surrounded by a zone of tympany and has a zone of tympany passing over it. (Steele.) Solid tumors of the mesentery are very movable, but otherwise very closely resemble retroperitoneal tumors. It should be possible, in most cases, to say whether the tumor is behind the peritoneum or within the peritoneal cavity, but of course the physical signs are not characteristic of retroperitoneal tumors alone (using the term in its restricted sense) but are found in any tumor arising in the retroperitoneal space and would therefore apply also to tumors of the kidney, the adrenal, remains of Wolffian ducts, pancreatic cysts, aneurism of the aorta, etc. A full discussion of the differential diagnosis is to be found in the papers by Steele.³

The treatment is surgical, for even those tumors which are histologically benign are always fatal,

unless they can be removed. The only exception to this rule is the solid non-malignant myo-fibroma or osteochondroma, which is extremely rare and may be recognized by the history, course and character of the growth. Retroperitoneal tumors in the pelvis present less formidable surgical difficulties than those in the upper abdomen because the anatomical relations are less complicated. In the first case reported here, the ureter and iliac vessels were easily seen lying upon the surface of the tumor. In the upper abdomen, however, the difficulties are much greater. I will beg the indulgence of the society in discussing a subject so elementary as anatomy, but the problems presented in operating on these tumors are largely anatomical. Retroperitoneal tumors are expansile in their growth and dissect along fascial planes and therefore the consideration of the fasciae of this region is of utmost importance. At the outer border of the kidney the fascia underlying the parietal peritoneum divides into two layers, one passing in front of and one behind the kidney. The name of Gerota, who described it in 1895, has become attached to this perirenal fascia. After thus splitting, the posterior layer, or retrorenal fascia, passes inward immediately in front of the lumbar muscles, and at the inner border of the psoas muscle it blends with the fascia covering the bodies of the vertebrae and intervertebral discs. It therefore lies behind the perirenal fat, the suprarenal gland, the renal arteries and veins and the aorta and vena cava. Above the level of the kidney it reunites with the anterior layer and becomes lost in the diaphragm. Extending downward both layers lie close together but do not actually fuse, and, becoming thinner and thinner, are lost in the loose areolar tissue of the iliac fossa.

The anterior layer or prerenal fascia lies beneath the peritoneum, to which it is loosely attached by a delicate areolar tissue. This attachment is so loose that in operating on one of these tumors it is easy to be deceived into thinking, after cutting through the peritoneum and seeing the smooth structure beneath, that another serous membrane has been encountered. This prerenal fascia forms the anterior capsule of the perirenal fat, and therefore bears that same relation to the tumors arising in that space. It passes inward in front of the renal vessels, aorta and vena cava and becomes continuous with the corresponding layer from the opposite side. It lies behind the colon (ascending and

descending) and behind the duodenum and pancreas. Where the peritoneum passes in front of viscera (e. g. duodenum or colon), it becomes separated from the prerenal fascia which lies behind these organs. The fascia passes behind the root of the mesentery and of the transverse mesocolon, thus shutting them off from the perirenal space. The superior and inferior mesenteric arteries, therefore, are outside the perirenal space except for the short distance between their points of origin in the aorta and the point where they enter the mesentery. The ureter throughout its course is within the perirenal space and is attached to the under side of the prerenal fascia. This attachment is quite firm and it is probable that in most cases this relationship would be maintained. It should be borne in mind, however, that in its upper course after it leaves the kidney the ureter must necessarily traverse the perirenal space for some distance. When ureter, veins or arteries pass through the tumor, they will always be found in the planes between the lobules of the tumor.

It is evident, therefore, that the prerenal fascia is a most important guide to follow, and fortunately, in a case of tumor behind it, the fascia tends to become thicker than normal and more easily followed. It can be safely incised at the outer side of the colon, thus giving entrance to the perirenal space, and so long as the surgeon is working within this space the dangers will be limited to certain areas, that is, in the mid-line where the mesenteric vessels leave the aorta, and in the region of the hilus of the kidney. A more detailed description of the anatomy and of the technique of operation is to be found in the article by Reynolds and Wadsworth, *Annals of Surgery*, 1906, vol. xlv.

Andrews (*loc. cit.*) reports favorable results in several cases of sarcoma from treatment by combined x-rays and radium, and states that in some instances the mass has entirely disappeared. He suggests this form of treatment as an aid to diagnosis where sarcoma is suspected.

The prognosis obviously depends upon the size and nature of the tumor. As has been already stated, it is uniformly fatal unless it can be removed. The mortality from operation is about 15 per cent and appears to be about as high for lipoma as for sarcoma. The anatomical relationships and fascial coverings of the tumor render its removal comparatively easy and safe while it is still small, or even if it is of considerable size if it has not

crossed the mid-line and therefore involved the mesenteric vessels, aorta and vena cava. It may be necessary to remove one kidney with the tumor and it is essential, therefore, always to determine the presence and functional capacity of the other.

Here, as in so many other conditions, successful treatment depends upon early diagnosis. Twenty-one of the series of 28 cases reported from the Mayo Clinic were found to be inoperable. These tumors are peculiarly insidious in their growth and the patient is lulled into a false sense of security because his tumor produces so few symptoms, and by the time it begins to cause symptoms it has become so large that removal is impossible.

Finally, as influencing the ultimate prognosis is the fact that many, if not all these tumors, lipomas included, are in reality mixed tumors. Among the 113 operated cases in Wahleldorf's series recurrence was noted in 15, and of these 15 five were lipomas, three fibro-lipomas, three fibro-myxolipomas, thus indicating that our usual distinctions between so-called benign and malignant tumors do not strictly apply to retroperitoneal tumors, for recurrence in lipoma and fibroma is contrary to our conception of the nature of these tumors.

The danger which is inherent in a tumor because of its malignant nature cannot be escaped; but the potency for harm which it acquires during months or years of insidious growth can be prevented by correct diagnosis which will point the way to earlier treatment.

DISCUSSION

DR. O. W. YOERC: When Dr. Baxter kindly asked me to lead the discussion of his paper, I asked him why he had chosen me, who had had so little experience along something of that nature. On looking up the literature I found that very little had been written, and the cases were few, as he has already stated. In speaking of sarcomas developed retroperitoneally, developed primarily from the peri-

toneal connective tissue, you impose a limitation that makes the group small. Most of these cases, from what I could gather, are lymphosarcomas or mycosis sarcomas. The lymphosarcomas seem to predominate and that is probably because you have the retroperitoneal lymph-glands and the lymph-glands in the mesentery, and that would probably also hold true of the mediastinal sarcomas, which are usually of lymphatic type.

As stated, the sarcomas as true types are hard to diagnose. They begin insidiously, without any pain, and by the time they demonstrate any symptoms there is a large tumor covering a considerable space. Lipomas, from what I could gather from the literature, will sometimes reach the weight of 20 to 50 pounds, and are usually not of the pure lipomatous type. The sarcomas when they do develop to that stage where a diagnosis is made—usually on exploratory incision—have reached a size so that they can hardly be removed. If they can be found early while still encapsuled, before metastasis develops, the chance of getting them out efficiently is better. But after they have become so large, the vascularity of the tumor and the proximity of the tumor to the larger vessels and the danger of hemorrhage, and also in removing them the danger of opening up avenues of metastasis and not being able to get all the tumor—due to all this, they are sometimes left in worse condition than if they had not been operated on.

It occurs to me that these tumors could probably be attacked more readily with the deep x-ray. We are now using it at Northwestern Hospital. We have had a deep x-ray machine there for the past year and a half, and the men there have had some very good results with sarcomas, kidney sarcomas and mediastinal sarcomas, with x-ray pictures showing large involvement. By treating them from different positions, the x-ray pictures—say of the chest—would be entirely negative afterwards. In these cases it would probably be to better advantage to the patient and to everybody else concerned if the diagnosis could be made and then treated with the deep x-ray therapy. The end results would probably be just as good. The end results either way are not good, but the patient would be alleviated of a lot of suffering and probably would get along better, because there is a certain element of danger in operating these cases. The mortality is fairly high in the line of tumors. I think that covers my meager knowledge of the subject.

DR. S. R. MAXEINER: I would just like to mention pneumoperitoneum as a diagnostic point in these retroperitoneal sarcomas. With the pneumoperitoneum and the patient lying on the face, with a large pillow or block or sandbag under the chest and under the pubes, a lateral picture should show an area filled with gas immediately in front of the spine. With the presence of a dense tumor this area is obliterated, and with the history and physical findings confirmed by the obliteration of this space in a pneumoperitoneum, some of these cases I think can be diagnosed and subjected to their x-ray treatment without the necessity of exploration for a specimen.

DR. R. E. FARR: I just want to accentuate the points made by Dr. Maxeiner regarding the employment of pneumoperitoneum in these cases. Dr. Santy showed a number of years ago the importance of this method in

differentiating retroperitoneal tumors. Another point I might mention is the comparative ease with which low-lying retroperitoneal tumors may be diagnosed by introducing the finger into the rectum.

DR. H. B. SWEETSER: I don't remember offhand having seen one of these tumors posterior to the peritoneum. Of course, we see a good many metastatic tumors that involve the glands, and I know that there is great difficulty in dissecting them out, and you never get them all out. If they can be subjected to the x-ray with any chance of success at all, I think that would be the preferable method.

DR. A. S. FLEMING (speaking by invitation): Not being a member of the Society, I was reluctant to take part in the discussion, but when Dr. Sweetser said that he had nothing to say on the matter it reminded me of the fact that I had seen a case that I suspected of being a retroperitoneal tumor, sarcomatous in type, in consultation with him some time ago. That also brings to mind the fact that in the last ten years, while associated with Hillcrest, I think I have had an opportunity to see, aside from the two cases that Dr. Baxter has brought up for consideration, three others, making a total of probably five of these retroperitoneal tumors, sarcomatous in type. Strange to say, one of these cases is alive after five years, and apparently better now than she has been for many years.

The problem of diagnosis depends a good deal on the point of origin, whether it is in the upper retroperitoneal space or in the lower lumbo-sacral region. This case in which the original diagnosis was made of an enlarged kidney, and later on suspected ovarian tumor, I had an opportunity to examine. Naturally anatomically it should have done just what it did; it stayed up there and displaced the viscera, pushed them out of the way, over to the left. It first presented itself as a large kidney, and then as it occupied the whole space and produced emaciation, it produced a typical picture of a large ovarian cyst. That was one of the later cases.

The other cases were tumors, originating in the lower portion of the retroperitoneal space, and presented surface signs appearing very much like tubercular abscesses will after they have followed the fascial planes either down into the pelvis, appearing in the groin, or through the sacro-sciatic notch. The case of Dr. Sweetser was of a young boy who had come here from Iowa and reported with a tumor appearing on the buttocks. He dissected down and I think followed that tumor as far as the sacro-sciatic notch. I had an opportunity to apply some radium in the pocket, but we could not accomplish more than temporary relief.

The first case of the kind that I recall appeared as a tumor thought to be a tuberculous abscess in the groin. Incision was made into the fluctuating mass, but instead of pus organized tissue was found, that on examination appeared to be sarcomatous. In that case we did not attempt to remove the different extensions of that growth because it went down into the pelvis, and it was very difficult to get access to. We were simply satisfied with applying radium as far as we could follow it. Unfortunately I lost track of that case, after following it for about six months.

The case that is now alive has a very remarkable history. She first reported to the hospital and an exploratory laparotomy was performed, a large retroperitoneal tumor impossible of removal was found. She went home and later returned for some relief from pressure symptoms. It then had made its appearance at the crest of the ilium. Then an incision was made and radium implanted in the tumor. She also received deep x-ray and responded very well. After several radiations she developed a sinus leading into the tumor that continued to discharge for a long time and it looked as though there was absolutely nothing further to do. She seemed to get radium fast and x-ray fast. About the time we decided she ought to engage an undertaker, she seemed to get better, and she has remained better ever since. That is a little over two years ago.

Another case was of a little girl who reported in her seventh year with a tumor appearing at the buttocks and loin with some flexion of the thigh. That responded to radium for over a year, then became radium fast and failed to respond, and the child died. The peculiar thing about this was that the little girl and the woman both came from the same neighborhood. So they don't seem to be as uncommon as one would be apt to think.

DR. A. W. ABBOTT: I want to call attention to one other condition; I didn't notice Doctor Baxter mention it, but I think he will recognize it because I think he helped me with at least one such case. That was a distended, or rather a misplaced, hydronephrotic kidney which was just above the pelvis. That brings in again the importance of using the usual catheter or pyelogram to make the diagnosis.

I think the Society is to be congratulated on having a paper like this; it is a real classic on this subject.

DR. S. H. BAXTER: In the matter of treatment, I did not go into the x-ray treatment very extensively, but these tumors when they are sarcomatous have in some instances eventually responded to deep x-ray therapy. Andrews in his report on the series from the Mayo Clinic has even gone so far as to suggest the use of x-rays in cases of undetermined tumors as a diagnostic measure, evidently in the same way that we used to use potassium iodide as a therapeutic test for the purpose of determining the nature of some obscure infections.

I think that ordinarily our usual means of physical examinations will enable us to make a diagnosis of a retroperitoneal tumor if only we have it in mind; but in a good many of the cases reported, the condition has not even been considered and that has been one of the reasons why I wanted to present this case because it is rather unusual and at the same time it may not be so unusual as we ordinarily think it is. If we have it in mind and exercise the ordinary means of diagnosis I think most of them can be diagnosed. However, Dr. Maxeiner's suggestion is useful in case the usual means fail and we are forced to resort to the extraordinary means for diagnosis.

The diagnosis is the main thing, because, as I stated in the paper, these tumors are uniformly fatal, regardless of their histological structure; even those that are so-called pure lipomas are always fatal unless they can be removed. So an early diagnosis is a matter of very great importance.

The Proposed New Minneapolis General Hospital

A medical school depends in large measure on available clinical material. The University medical school, not having a large hospital, has utilized half the patients in the Minneapolis and St. Paul City Hospitals for some years past and is likely to pursue the same practice for years to come. Both of these city hospitals are inconveniently located for undergraduate work and with the contemplation of a much needed new Minneapolis general hospital the proposition of locating the new structure near the University campus has been brought forward. This is a matter of interest and importance to the medical men of the state and the medical school itself and should be viewed from an impartial standpoint.

The present Minneapolis General Hospital in the congested downtown district of Minneapolis is too small for the growing city. Like many such insti-

tutions, it is the complex and inconvenient result of combining buildings of various ages, constructed without any original far-reaching plan. It is confined to one small block of land and is in a rather smoky and dirty section. The Superintendent and Board of Welfare are certainly correct in their decision that something must be done soon to provide new buildings on a new site.

But where should such a hospital be placed? Its primary function is the care of the poor of the city. For this purpose it should have good physical surroundings; but above all it should have the best staff and nursing service that can be provided. Doubtless, like all the great charity hospitals, it will be dependent on a voluntary staff. It should be placed where it can be reached easily by the busy men of the medical profession. This shuts out distant suburban proposals. The river bank near the Medical School is beautiful and accessible.

A second important function of the hospital is medical and nursing education. By arrangement with the city the University nominates half the staff. Twelve medical students live at the hospital all the time and serve as junior interns. Required clinics, elective clinics, clerkship and extern work of great educational value are carried on there for both Juniors and Seniors of the Medical School. The Pathological Department of the school conducts a weekly pathological conference at the hospital which is of value alike to the staff of the hospital, to the University and to visiting doctors. The interests of undergraduate medical teaching (and this means the broader interests of health and medical service in the city and state) dictate that the new hospital be located as near the Medical School as possible.

The nursing school of the General Hospital is part of the University Nursing School. The pupil nurses get their first quarter's instruction at the Medical School. After that they get practical instruction at the Hospital but go to the University for certain classes. This important work is hampered by distance and would be much facilitated by a location on the campus or across the street from it.

Graduate medical teaching presents the same problem and the same plea. When doctors come to the city to see clinics and take "refresher" lectures their time should be saved. For work toward advanced degrees in clinical specialties

under the Minnesota plan, proximity of clinics and laboratories would spell opportunity and call excellent students. The effect on the staff of the hospital would be good. The University offers to place at the disposal of the hospital its laboratories, library and scientific investigators.

It is not proposed that the location of the hospital near the University would in any way affect its management or policy. The city would control it in every way as it does now. The reflex advantages of co-operation would be mutual. But both the University and the Hospital would retain entire autonomy and independence. This, of course, is legally necessary.

The Board of Welfare has signified its willingness to accept a site near the University. The proposition has met the approval of the Medical Alumni Advisory Board. The University has considered offering a site on the campus. This could only be done with the approval of the State Legislature. The second proposal is that the University through gifts provide other land near the campus on which the hospital may be built. The latter is, perhaps, the better plan and will probably be adopted.

There can be no doubt that this proposition is the most important one in its bearing on medical education that has arisen in Minnesota in many years. If it is settled wrong and the General Hospital is placed at a distance, the mistake can never be rectified. If it is settled right and the immediately needed 600 or 800 beds, followed as the city grows by larger numbers, are placed close to our already excellent medical school, a permanent forward step will be taken, a step toward that coveted goal of making the Twin Cities one of the great medical centers of the country.

Facts and Refraction

A recent article from the pen of our friend, Dr. Brady, concerning the use of cycloplegics in refraction precipitated a spirited controversy in the columns of one of the St. Paul daily papers between two local opticians.

Dr. Brady had mentioned the necessity of using "drops" to refract properly most individuals under forty years of age. This article brought out quite a strenuous opposition from an optician who has

been warning the public in his advertisements for some time past of the danger of "drops" and their uselessness, quoting many alleged utterances of authorities to that effect. A reply was published from a second optician, denying the existence of such danger when "drops" are used under the guidance of qualified and competent oculists, insisting on the necessity of using "drops" in selected cases of latent errors, ciliary cramp, etc., and also stating that in his opinion only the law prevented most opticians themselves from using "drops" in refraction. He also dwelt on the advantage of a fundus examination by men medically trained in the recognition of diseases of the eye.

When medical facts are thus distorted and advertised to the public, it is incumbent upon someone to take up the cudgel. In this instance the unpleasant task was spared the medical profession by the reply of the second optician, who by the way limits himself exclusively to filling prescriptions. Here is one instance where the temptation to distort facts in order to do more business was too much for one optician. The desire to sell a pair of glasses on the part of many an optician doubtless inflicts glasses unnecessarily upon many a child who has a slight refractive error. Human nature is so frail that it is well to divorce the two sciences.

The fact of the matter is that most opticians do not concur in the opinion voiced by their confrere regarding the undesirability of a cycloplegic in refraction. At least one optometrist in this section has employed a "Doc" to "stick around" for the purpose of using drops in the eyes of his clients, the distinct advantage of which he advertised in the papers.

Refraction affords numerous opportunities to detect the presence of eye pathology. The eye is not simply a mechanical lens and screen. Take it all in all, the individual ignorant of the diseases of the eye cannot render as great a service as one on the outlook for evidences of local or constitutional diseases expressed in the eye.

No part of a medical examination is so certainly worth while, when indicated, as a fundus examination. Every refraction in the hands of a competent oculist includes this. It is not too much to say that in refraction, more often evidence of unsuspected local and constitutional disease is found than in any other kind of a medical examination.

St. Paul Clinic Week

The dry clinic more than the wet is to be the outstanding change in the program as arranged for St. Paul Clinic Week this year. Clinics and symposia have proven themselves of most value in medical programs and clinics will occupy each morning with a symposium each afternoon. Following the symposia, opportunity will be afforded visitors of hearing outside speakers of national prominence.

A glance at the program which appears elsewhere in this issue will convince one that the selection of subjects has been a happy one. The morning clinics, although fewer this year, are not being published in the journal but will be posted daily at headquarters.

The average physician is a busy man. He cannot take an extended postgraduate course, but he can derive a lot of practical information from clinical meetings of this sort.

Dr. E. W. Buckley

We pause on the threshold of the seventh year of the existence of the journal to pay tribute to the passing of Dr. E. W. Buckley of St. Paul, who may be fittingly termed the father of MINNESOTA MEDICINE.

The story of how the journal was instituted by action of the House of Delegates in Duluth in 1917 is an interesting one. The association committee of five members appointed to investigate the proposition of launching an association journal reported unfavorably at this annual meeting. Dr. Buckley, a member of the committee, after a thorough investigation of conditions in other states, was convinced that the size of the association warranted the publication of its own journal. This opinion, which amounted to a conviction, led him to present a minority report and his presentation of the case led the House of Delegates to undertake the publication of MINNESOTA MEDICINE.

That MINNESOTA MEDICINE has weathered its first six years of existence is fitting tribute to the judgment of Dr. Buckley.

MISCELLANEOUS

WHY DOCTORS BUY WORTHLESS AND FRAUDULENT SECURITIES

BY SAMUEL O. RICE

Educational Director, Investment Bankers Association of America

Physicians who number bond men, investment bankers, among their patients frequently complain that bond men squander their health.

"The heads of three bond houses," my family doctor said to me the other day, "are patients of mine, they and several subordinate officers of other houses, and I'll be hanged if they aren't more careless with their health than is all the rest of my practice put together. They'll work like demons for months at a time and then try to make up for the loss of daily exercise and common sense routine by trying to crowd a year's recreation into a few weeks. They'll eat, and drink, too, a lot of stuff that's bad enough at home, but is doubly damaging when they take frequent business trips with irregular hours, heterogeneous food and the unavoidable strain of an exacting business. They are the worst spendthrifts of health that I know among intelligent men."

"At least they are not as bad as doctors," I replied to my friend's amazement. "When they need medical service you've got to admit they don't go to quacks for it. They go to the reputable profession and to recognized specialists don't they?"

"What has that got to do with it?" the doctor asked. "Physicians can't avoid irregular hours, but they're not—"

"The argument is," I interrupted, "on the use of common sense, isn't it? You say that bond men don't use common sense about health. But as lax as they are in that, they are not as lavish in squandering health as physicians are in squandering money in so-called investments. Bond men at least exercise common sense enough to realize that it requires a doctor to exercise medical judgment for them. How many physicians realize that it requires a 'doctor' of investments to select investment securities dependably? Ever hear of an investment banker being swindled by a quack practitioner? How often are physicians swindled by quack investment schemes?"

"There are just two reasons why doctors, as a class, are notable for buying worthless securities. One of them is their failure to realize that in seeking good, sound investments you have to do exactly the same thing you do in seeking health—consult an honest, competent practitioner."

"What's the other reason why we buy worthless securities?" my friend asked with a smile. "Because doctors are not business men?"

"That's the reason usually given, but I don't believe there's anything to it. The second reason is too much optimism."

"There isn't one of you who doesn't believe that next year's practice is going to be a whole lot more remunerative than this year's. Your first years of practice, when you started with nothing and gradually built up your income, taught you that. It's firmly fixed, perhaps subcon-

sciously, in every doctor's mind. It's a life thought-habit of the profession, besides being a somewhat common human trait.

"Well, if things are going to be better next year, I'll just take a few hundred dollars of the stock of this patent electrical device or in that new serum outfit," you argue. Thousands of little oil and mining companies have been organized in the last few years among little groups of friends in every town, city and hamlet in the United States and have blown up after losing the money put into them. I'll wager that in every such little venture 90 per cent of them have had one or more physicians as stockholders. As a profession, you are so confoundedly optimistic you let your optimism run away with your better judgment, and you accumulate a lot of nondescript interests in a number of things you know nothing about and that have little or no value when your widow tries to realize on them."

"Yes, I guess some of that is possibly true," my friend admitted.

"True—of course, it's true. Six months ago I had a little ready money and I asked you to send me your bill. I telephoned you twice. I got that bill last week, six months after I had put my little ready money into some sound investments selected by an investment specialist and not by inexperienced friends or an easy-talking promoter. Now, when I'm shy of cash, you optimistically send me a bill. I'll bet you \$4 you are going to buy a new car. You are careless about collections, partly because it is in the code of your profession not to be mean and grasping. I honor you for that, but your eternal optimism is also a part cause. Oh, you say, I'll get more money next month; if not from Jones, from Smith. And you base your investments on the same kind of careless optimism.

"I'm serious in this, Roy. You wouldn't have a bit of sympathy for me if I disregarded the common sense that the medical profession has patiently drummed into the public for years, the fact that the public must consult reputable, competent medical advisers. You'd have a silent contempt for me if I let some quack or gaudy fake practice in my family or if I answered a cure-all medical advertisement.

"The so-called intelligent public has learned its lesson in medicine, that of consulting reputable practitioners. It is just as important that the medical public learn the same lesson as applied to investing on money. You nor no other physician can judge an investment security dependably, if you continue attending to your legitimate vocation. Even if you had time to do it, very frequently you haven't the facilities to determine the worth of a security. Investment banking is such a highly specialized calling that I doubt if any man has the ability to perform the investment banker's work without adequate training in the work.

"Physicians should be the first persons in the world to recognize this fact, but strange to say, many of them do not. As a consequence, they are notably heavy losers in bad investments. And the cure for this bad investment condition is the same as in human pathological conditions—consult the reputable specialist who is competent to treat the case."

COMMUNICATIONS

Fergus Falls, Minn., December 19, 1923.

To the Editor:

The "Proceedings of the House of Delegates," published in the December number of MINNESOTA MEDICINE, should be read by all. The president's address and the committee reports are full of very valuable suggestions. It is a duty and a pleasure to give them careful reading and full consideration. In no other way can one keep in touch with the society's accomplishments and aspirations.

At this time, I wish particularly to call attention to the report of the Committee on Medical Education and Hospitals. Their conclusions were reached after exhaustive study and investigation.

Our medical school is on the verge of becoming one of the greatest in the world. To this end the whole-hearted support of the profession is greatly needed. The recent generous gifts are notable. There are reasons for thinking that the Rockefeller Foundation will meet us half way.

Note the following recommendations of the Committee:

(1) That a state-wide campaign be inaugurated to induce wealthy patients and friends to donate funds to the medical school.

(2) That an effort be made to have the Minneapolis General Hospital placed on the campus.

(3) That plans be perfected for carrying graduate medical instruction to various parts of the State. This is being successfully carried on in several states, notably Pennsylvania.

(4) That the courses for practitioners at the University be extended. That they be given wide publicity and the support of the county societies.

(5) That the profession at large support the law which permits state or county to stand the cost of hospital care at the University Hospital, thus removing this item from the University educational budget.

W. L. BURNAP.

OBITUARY

DR. EDWARD W. BUCKLEY

Dr. Edward W. Buckley of St. Paul was born on a farm in Washington County near Stillwater in 1859. He died September 26, 1923, at St. Joseph's Hospital, St. Paul.

When a child he moved with his parents first to Minneapolis and later to Mankato, where he attended the grade and high schools. He attended Holy Cross College at Worcester, Massachusetts, but left before completing his course and took up telegraphy. Three years later he began the study of medicine at the College of Physicians and Surgeons in New York City. On receiving his medical degree in 1888 Dr. Buckley spent a year at the City Hospital on Blackwell's Island. It was during undergraduate days that a friendship began between Dr. Buckley and his classmate, the late Dr. J. W. Bettingen—a friendship destined to be lifelong. At the same time the late Dr. Arthur J. Gillette

was doing post-graduate work in the New York Hospital for Ruptured and Crippled Children and the three St. Paul physicians became fast friends.

On completing his medical training Dr. Buckley came directly to St. Paul, locating in a rather sparsely settled and poorer district of the city, on Case street, where he engaged in practice. Early in his career he became interested in fraternal insurance and became active in the Independent Order of Foresters and the Ancient Order of the Hibernians. Later he held various offices in the order of the Knights of Columbus and as supreme physician displayed his genius for organization, and his perfection of the insurance department of the order led to his recognition as an authority in the medical conduct of these societies.

As the organization of the Knights of Columbus increased in size their medical supervision demanded more and more of Dr. Buckley's time and of late years all his activities were directed to this class of insurance. Notwithstanding the increasing demands upon his time he still found time to advise, help and console many of his old time patients.

In 1892 Dr. Buckley was married to Miss Mary Kennedy of St. Paul, who, with a daughter, Margaret, survives him.

In 1893 Dr. Buckley was secretary of the Ramsey County Medical Society and in 1919 became its president. As a member of the Board of Trustees of the Building Fund of the society his experience and advice in financial matters were always greatly valued. It was largely due to the force of his personality that MINNESOTA MEDICINE was launched in 1918 as the Journal of the Minnesota State Medical Association.

For years he was a member of the staff of St. Joseph's Hospital and a few years ago at the reorganization of the staff he was elected Chief of Staff.

During the World War Dr. Buckley went to France and had an important part in establishing and organizing the activities of the Knights of Columbus among the soldiers. In recognition of his war work he was made Chevalier of the Legion of Honor and was personally decorated by Marshal Foch. In the summer of 1921 as a member of the commission which presented the city of Metz with a statue of Lafayette, a gift from the Knights of Columbus, he again visited France and shared the regal entertainment extended the commission by the French government.

It was on this occasion that Dr. Buckley was decorated with the Legion of Honor and with the similar decoration as a Commander of the Order of Morocco, by General Lyanty. For war work in Italy, instituted by the Knights of Columbus during the war, he was made a Knight of Saint Gregory by Pope Benedict VII.

Three years ago Dr. Buckley was appointed chairman of the National Tuberculosis Commission of the Knights of Columbus, which work was under consideration at the time of Dr. Buckley's death.

Dr. Buckley was an honorable and upright member of the medical profession, always ready to take a vigorous part in public affairs affecting the profession and people at large. Being somewhat of a parliamentarian, he rather enjoyed enforcing Robert's Rules of Order when presiding over a gathering. He had a special gift for summing up a situation and presenting in his forceful way his opinion of the

correct procedure. His ability as a public speaker enabled him to be a great leader in his chosen field of medical activity but his firm exterior concealed a sympathetic nature which was well known to his many friends.

DR. SAMUEL C. McCORMICK

Dr. Samuel Carson McCormick, aged 86, said to have been the oldest practicing physician in the state, died November 17, after an illness of seven months.

Doctor McCormick was born in Pennsylvania, Sept. 8, 1837. He was a graduate of Lewisburgh university, now Bucknell college. In 1861 he graduated from Jefferson Medical college and was appointed first assistant surgeon in the United States army and served throughout the war. He is survived by his widow and two sons, C. P. McCormick, Seattle, Wash., and W. S. McCormick, of Duluth.

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

ST. PAUL CLINIC WEEK

The fourth annual St. Paul Clinic Week will be held Tuesday to Friday, inclusive, January 15 to 18, 1924. Headquarters will be at the St. Paul Hotel.

Clinics will be held at the various hospitals each morning during the session. The afternoons will be devoted to the following symposia and addresses by eminent specialists:

TUESDAY AFTERNOON

Symposium—Intestinal Obstruction

Dr. E. M. Jones, St. Paul—Etiology

Dr. F. J. Plondke, St. Paul—Surgical Differential Diagnosis

Dr. J. A. Lepak, St. Paul—Medical Conditions Simulating

Dr. A. MacLaren, St. Paul—Treatment

Address—Surgical Reconstruction of Certain Excretory Ducts

Dr. Lewis L. McArthur, Chicago

WEDNESDAY AFTERNOON

Symposium—Life Insurance

Dr. J. Allen Patton, Medical Director, The Prudential Life Insurance Company of America

Dr. F. L. Grosvenor, Medical Director, The Travelers Insurance Company of Hartford, Conn.

Dr. Robert L. Rowley, Medical Director, The Phoenix Mutual Life Insurance Company

Dr. D. E. W. Wenstrand, Medical Director, The Northwestern Life Insurance Company of Milwaukee

Address—Reconstructive Surgery and Industrial Insurance
Dr. Harry E. Mack, Chicago

THURSDAY AFTERNOON

Symposium—Irregularities of the Heart

Dr. C. N. Hensel, St. Paul

Dr. E. T. F. Richards, St. Paul

Dr. Harold Richardson, St. Paul

Dr. Harry Oerting, St. Paul

Address—Clinical Problems of Chronic Suppuration of the Middle Ear

Dr. George E. Shambaugh, Chicago

FRIDAY AFTERNOON

Symposium—Etiology and Diagnosis of Diseases of the Kidney and Ureter

Dr. E. T. Bell, Minneapolis

Dr. Arnold Schwyzer, St. Paul

Dr. E. T. Herrmann, St. Paul

Dr. F. E. B. Foley, St. Paul

Diagnostic Clinic in Prostatism

Dr. W. F. Braasch, Rochester, Minn.

Wednesday evening a buffet supper has been arranged to be followed by an informal stag entertainment.

Thursday evening the annual meeting and banquet of the Minnesota Academy of Ophthalmology and Otolaryngology will be addressed by Dr. George E. Shambaugh, of Chicago. This meeting is open to all physicians interested.

The final program will be placed in the mail not later than January 5th.

THE MINNEAPOLIS SURGICAL SOCIETY

MINNEAPOLIS, MINN.

January 10th, 1924

NORTHWESTERN HOSPITAL

9:00 to 12 A. M.

Operative Clinics

DR. MANN	DR. LAW	DR. BULKLEY
DR. POPPE	DR. YOERG	DR. NORDLAND

Followed by Pathological Conference

DINNER AT MINNEAPOLIS ATHLETIC CLUB

6:30 P. M.

HENNEPIN COUNTY MEDICAL SOCIETY ROOMS

8:00 P. M.

"Surgery of the Gall Bladder"

By DR. E. S. JUDD

ROCHESTER, MINNESOTA

All medical men are invited to attend the dinner and all parts of the program.

THE MINNEAPOLIS, ST. PAUL & SAULT STE. MARIE RAILWAY SURGICAL ASSOCIATION

The Minneapolis, St. Paul & Sault Ste. Marie Railway Surgical Association held a full two-day scientific session on December 11 and 12, at Minneapolis, Minn., presided over by President Dr. John V. R. Lyman, Eau Claire, Wisconsin.

The following officers were elected for the ensuing year: President, Dr. F. Gregory Connell, Oshkosh, Wis.; vice

president, Dr. George G. Eitel, Minneapolis, Minn.; secretary-treasurer, ex officio, Dr. John H. Rishmiller, Minneapolis, Minn.

The next place of meeting was left to the discretion of the officers.

RICE COUNTY MEDICAL SOCIETY

Members of the Rice County Medical Society held their annual meeting in Northfield, Friday, November 20. The paper of the evening was read by Dr. Walter Rumpf, of Faribault, his subject being "The Treatment of Diabetes."

Officers elected for the coming year are: President, Dr. F. M. Babcock, Northfield; first vice president, Dr. F. J. Lexa, Lonsdale; second vice president, Dr. C. J. Plonske, Faribault; secretary-treasurer, Dr. C. M. Robilliard, Faribault.

SCOTT-CARVER COUNTY MEDICAL SOCIETY

At the annual meeting of the Scott-Carver County Medical Society held at Jordan, December 6, 1923, the following officers were elected for the coming year: President, Dr. F. J. von Bohland, Belle Plaine; vice president, Dr. F. H. Buck, Shakopee; secretary-treasurer, Dr. H. W. Reiter, Shakopee. Dr. F. H. Buck was elected to the board of censors. Dr. H. W. Reiter was chosen to act as delegate to the annual meeting of the State Medical Association with Dr. John Landenberger, of New Prague, as alternate.

STEELE COUNTY MEDICAL SOCIETY

Dr. J. F. Smersh, of Owatonna, was re-elected president of the Steele County Medical Society at the annual meeting and dinner held in Owatonna, November 20, 1923. Other officers elected for the coming year are: Vice president, Dr. B. Melby, Blooming Prairie; secretary, Dr. A. B. Hart, Owatonna; treasurer, Dr. F. M. Smersh, Owatonna. Dr. J. H. Adair, Dr. J. W. Andrist and Dr. A. B. Stewart, all of Owatonna, were elected censors.

Dr. Charles S. McVicar, of Rochester, the principal speaker of the evening, gave an illustrated lecture on "The Diagnosis of Dyspepsia."

WASHINGTON COUNTY MEDICAL SOCIETY

The Washington County Medical Society held its annual meeting at Stillwater, Tuesday evening, November 13, 1923. Dr. H. K. Van Norman, superintendent of the Miller Hospital, St. Paul, addressed the society on the subject of hospitals with special reference to hospital staffs. A report of the state medical meeting was given by Dr. J. W. Stuhr, as delegate.

Officers for the ensuing year were elected as follows: President, Dr. F. G. Landeen; vice president, Dr. J. W. Stuhr; secretary-treasurer, Dr. R. J. Josewski. Dr. D. Kalinoff was elected to membership on the board of censors, Dr. A. E. Brown as delegate to the 1924 meeting of the State Medical Association, and Dr. E. B. Freligh as alternate.

OF GENERAL INTEREST

Dr. O. S. Werner, formerly of South Haven, has located in St. Hilaire for the practice of his profession.

Dr. A. E. Mark, St. Paul, has moved to Los Angeles, Cal., where he will continue the practice of internal medicine.

Dr. Stuart H. Anderson, formerly of Wells, has become associated in the practice of medicine, with Dr. A. E. Johnson at Red Wing.

Dr. J. S. Kilbride, of Canby, who has been doing post-graduate work in surgery in the hospitals of Chicago, has returned to his practice in Canby.

Dr. Carl Goehring, formerly of the Mayo Clinic, Rochester, is now located in Steubenville, Ohio, where he will practice general medicine.

Dr. and Mrs. Haldor Sneve, of St. Paul, who have been in Santa Barbara, Cal., the past few months, have moved to San Diego, where they expect to spend a year.

Dr. R. E. Farr, Minneapolis, addressed a meeting of the McLeod County Medical Society, December 13, on "Local Anesthesia; Its Technic and Clinical Applications."

Dr. Robert Guilmette, of Minneapolis, has become associated in the practice of medicine with Dr. A. W. Swedenburg, of the Swedenburg Hospital at Thief River Falls.

Dr. H. J. Hanson has disposed of his practice at New London and is now located in Minneapolis. Dr. H. S. French, formerly of Grove City, has taken over the practice at New London.

A group of fifty students, three of whom are women, was graduated from the medical school of the University of Minnesota at the all-university commencement exercises of the fall quarter in 1923.

Dr. F. C. Rodda, Minneapolis, associate professor of pediatrics at the University medical school, has been appointed acting head of the pediatrics department to succeed Dr. Clemens Pirquet, of Vienna, who resigned in October after holding the position less than a month.

Dr. H. P. Ritchie, of Saint Paul, was elected secretary-treasurer of the Western Surgical Association at the annual meeting held in Colorado Springs, Colorado, December 6 to 8, 1923. Dr. Donald McRae, of Council Bluffs, Iowa, was elected president of the association.

Following a period of five years of service as medical superintendent of Fair Oaks Lodge Sanatorium at Wadena, Dr. George McLeod Waldie has resigned, his resignation to become effective January 1, 1924. Dr. Waldie will be succeeded as head of the sanatorium by Dr. J. J. McKinnon, of Wadena.

Dr. M. George Milan, formerly medical director of the Oak Park Tuberculosis Sanatorium at Thief River Falls, is now a member of the medical staff of the Warren Hospital, Warren, Minnesota, where he assumed his duties January 1, 1924. Dr. Milan succeeds Dr. W. W. Holley, who resigned recently to go to California.

Dr. Harold Rypins, of Minneapolis, has been granted a

year's leave of absence from the University of Minnesota to act as secretary of the New York State Medical Board. Dr. Rypins has in charge the promotion of legislation requiring annual registration of all practitioners in New York. In this way it is hoped that all charlatans shall be driven from the state.

Two Minnesota physicians, Dr. Henry F. Helmholtz, of Rochester, and Dr. A. J. Chesley, of St. Paul, were recently elected as directors of the American Child Health Association, of which Herbert Hoover is president. Five others elected to the directorate at the same time are Dr. Louis I. Dublin and E. L. Thorndike, New York; Christian A. Harter and C. O. Williams, Washington, D. C.; and Dr. Henry F. Vaughan, Detroit, Michigan.

At a meeting held in St. Paul the latter part of November, 1923, for the purpose of organizing the Great Northern Railway Surgeons Association, the following physicians were elected to office in the society: President, Dr. P. A. Baxter, of Libby, Montana; first vice president, Dr. R. N. Simpson, Winnipeg; second vice president, Dr. J. N. Cunningham, Spokane, Wash.; third vice president, Dr. Roscoe Webb, Minneapolis; secretary-treasurer, Dr. Harold Hulsiek, St. Paul.

In October, the St. Louis Star succeeded in exposing a ring of diploma venders in St. Louis and Kansas City. The investigation has extended to Connecticut, Arkansas and other states where eclectic boards of medical examiners appear to have found an open door. No purchaser of a bogus high school or medical diploma could pass a properly conducted license examination and this outrageous procedure is simply additional proof of the necessity of a medical examining board of professional standing and personal integrity. Minnesota has not been implicated in this scandal.

The method of sending indigent patients to the University hospital is not generally understood. Any town or county official may recommend that a patient be sent to the hospital. The county commissioner will then have a physical examination made and assure himself that the financial status of the patient warrants state and county (the county pays half the expense) support. Application forms may be obtained from the University hospital superintendent. The hospital will not take mental cases, persons with acute tuberculosis, orthopedic cases, contagious diseases nor chronic cases which will not be relieved by treatment over a definite period.

At the meeting of the Board of Regents of the University held December 11, 1923, the following officers were re-elected: President, Fred B. Snyder; vice president, M. M. Williams; secretary, A. J. Lobb.

Fellowships at the Mayo Foundation, Rochester, were granted by the Board to the following: John G. Anderson, Frederick A. Bothe, Donnell B. Cobb, Granville S. Delamere, Jackson K. Holloway, Russell O. Lyday, Robert Mailer, Alfred L. Mayfield, Norman B. Muhme, Samuel H. Nixon, John Wesley Stinson, Isaac M. Webber, Joseph Daly, Howard L. Sargeant, Knut H. Houck, Christian J. Rohwer, John F. Gipner, Ellis B. Gray, Lillian M. Mayer, Samuel W. Becker, Stephen T. Parker and Donnan B. Harding.

A service to the entire state of Minnesota will be performed by the Child Guidance Clinic, which was opened Nov. 1, at the University of Minnesota for the experimental year during which it will be financed by the Commonwealth Fund of New York.

The purpose of the clinic is to examine, study and suggest treatment for children of abnormal behavior, so that remedial care can begin in early youth before the troubles become too firmly rooted.

Dr. Lawson Lowry has been appointed director. Working with him he will have a staff of psychologists, social workers and clerks, as well as a number of interested members of the medical profession.

Social agencies or the authorities in any community in Minnesota may send children to the clinic for observation. Parents or guardians also may present children whom they would like to have examined.

Following the demonstration year during which the clinic will be at the University, both Minneapolis and St. Paul will establish permanent clinics for child guidance according to present plans.

Attention is again called by the Collector of Internal Revenue to the necessity of exchanging narcotic order forms issued before 1923 for the current issue, as old forms will not be honored after January 1, 1924. In fairness to the druggists it is incumbent on physicians to comply with this regulation. Old forms should be sent to L. M. Willcuts, Collector of Internal Revenue, Federal Bldg., St. Paul, with the sum in cash of two-thirds of a cent for each old form which has been used in the old book.

According to the Harrison Narcotic Law prescriptions issued habitues to keep them comfortable and not in an attempt to cure the habit are illegal. Two exceptions to this situation are cited: (1) in incurable diseases such as cancer, tuberculosis, etc.; (2) in aged and infirm addicts where withdrawal would result in death. In the first mentioned exception endorsement should be made on the prescription that patient is suffering from an incurable disease or (Exception (2) article 117): in case of the second exception statement should be made on the prescription that patient is infirm and aged and drug is necessary to sustain life, or (Exception (2) article 117).

The bureau has never sanctioned the so-called reductive ambulatory treatment of addiction, and rightly so.

The Army is making an intensive campaign for procuring officer material for the reserve corps of every branch of the service. A communication has been received recently from the Surgeon General calling attention to the importance of organization of an adequate reserve corps in the medical corps in order to be prepared, medically speaking, for any national crisis. The reserve corps cannot be called into active service unless a national crisis arises.

The medical reserve corps has room for several thousand more officers—especially first lieutenants and captains. Appointments of first lieutenants may be obtained without examination by graduates of recognized medical schools, who have passed National or State Board examinations. A former medical officer of the Army desiring appointment in a higher grade than that he held while in the service must appear before a board of officers for examination. The stringent requirements heretofore in effect in such cases

have been lessened somewhat. A former first lieutenant in the medical corps, during the World War, who served satisfactorily on active duty in that grade for more than six months is eligible for appointment by examination to the grade of captain; also are those officers over 31 years of age now, who served satisfactorily on active duty in the grade of first lieutenant for less than six months. Those former captains of the Army, who served satisfactorily on active duty for at least one year and held the grade of captain for at least three months and whose records indicate that they possess the necessary qualifications for a field grade, may apply for the grade of major. Those ex-medical officers, who served satisfactorily on active duty for at least one year, held the grade of major for at least three months and whose records indicate that they possess the necessary qualifications for the higher grade, are eligible for appointment by examination to the grade of lieutenant-colonel.

Communications may be addressed to Major R. W. Whittier, 400 Kasota Bldg., Minneapolis, Minn.

A dinner was given December 4, 1923, at the Hotel Commodore, New York City, by the Rockefeller Foundation in honor of a group of health officers representing eighteen foreign governments, who for the past three months had been in the United States under the auspices of the Health Section of the League of Nations for the study and observation of various types of public health organization.

Dr. George E. Vincent, President of the Foundation, presided at the dinner. Dr. William H. Welch, Director of the Johns Hopkins University School of Hygiene and Public Health, in the absence of Dr. F. F. Russell, General Director of the Foundation's International Health Board, extended greetings to the foreign visitors on behalf of the public health workers of the United States. The other speakers were Mr. John D. Rockefeller, Jr., Chairman of the Board of Trustees of the Rockefeller Foundation; Dr. Hugh S. Cumming, Surgeon General of the United States Public Health Service; Dr. Linsly R. Williams, Managing Director of the National Tuberculosis Association; Dr. W. S. Rankin, State Health Officer, North Carolina; and Dr. Norman V. Lothian, of the Health Section of the League of Nations.

The visit of these health officials to the United States represents the third general interchange of public health personnel arranged by the Health Section of the League of Nations. The first took place in Belgium and Italy in 1922, and the second in England and Poland during February, March and April, 1923.

In the present group are representatives delegated by their respective governments, among them many of the most eminent sanitarians in the world, from France, England, Italy, Russia, Poland, Spain, Holland, Belgium, Greece, Yugoslavia, Germany, Switzerland, Norway, Mexico, Salvador, Brazil, Chile and Canada.

The system of international interchange of public health personnel was made possible by a contribution to the Health Section of the League of Nations from the International Health Board of the Rockefeller Foundation, amounting to \$60,080 a year, for a period of three years. The object of the plan is to bring the public health personnel of different countries into closer relationship with each

other, to effect a mutually profitable exchange of views on health subjects, to make comparative studies of health organization and legislation in different countries, and to promote international co-operation in establishing uniform standards for public health regulations.

NEW AND NON-OFFICIAL REMEDIES

In addition to the articles enumerated in our December issue, the following have been accepted by the Council on Pharmacy and Chemistry:

ABBOTT LABORATORIES:

Butesin.

E. BILHUBER, INC.:

Afenil.

Ampules Afenil.

CUTTER LABORATORIES:

Diphtheria Antitoxin Globulin.

Glycerinated Vaccine Virus.

Gonococcus Vaccine.

HOFFMANN-LAROCHE CHEMICAL WORKS:

Iodostarin.

Chocolate Tablets Iodostarin-Roche.

Chocolate Tablets Iodostarin-Roche 0.25 Gm.

PARKE, DAVIS & CO.:

Carbon Tetrachlorid (Human Use)-P. D. and Co.

Butesin.—*n*-butyl-para-aminobenzoate. Butesin is the normal butyl ester of 4-aminobenzoic acid. The actions and uses of butesin are similar to those of benzocaine (anesthetin), which is the ethyl ester of 4-aminobenzoic acid (see New and Non-official Remedies, 1923, p. 41, Anesthetics, Local, Difficultly Soluble). Butesin is used as a dusting powder, either pure or diluted. It may be used in the form of troches, ointment, suppositories or dissolved in a fatty oil. Butesin is a white, crystalline powder, odorless, tasteless, almost insoluble in water, but soluble in alcohol, chloroform, ether and in fatty oils. The Abbott Laboratories, Chicago. (Jour. A. M. A., Nov. 3, 1923, p. 1523.)

Diphtheria Antitoxin Globulin.—This product (see New and Non-official Remedies, 1923, p. 283) is also marketed in syringes containing 20,000 units. Cutter Laboratory, Berkeley, Calif.

Glycerinated Vaccine Virus.—This product (see New and Non-official Remedies, 1923, p. 293) is also marketed in packages containing one capillary tube. Cutter Laboratory, Berkeley, Calif.

Gonococcic Vaccine.—A gonococcic vaccine (see New and Non-official Remedies, 1923, p. 304) marketed in vials of 5 c.c. and 20 c.c., each cubic centimeter containing 500 million cocci. Cutter Laboratory, Berkeley, Calif. (Jour. A. M. A., Nov. 17, 1923, p. 1693.)

Afenil.—Calcium chloride urea. A molecular compound of calcium chloride and urea. Afenil has the actions of calcium chloride. It is claimed that when afenil solutions are administered intramuscularly or intravenously, the drug is better tolerated and less irritating than calcium chloride. It is claimed that the intravenous administration of afenil

is indicated in hay fever, asthma and other diseases of the respiratory tract in anaphylactic conditions, skin rashes, urticarias and as a means of preventing severe arsphenamine reactions. Afenil is marketed in ampules containing 10 c.c. of a 10 per cent solution of afenil. E. Bilhuber, Inc., New York.

Silver Nitrate Solution in Capsules-P. D. and Co.—An aqueous solution of silver nitrate contained in capsules composed of beeswax with an inner lining of a hard paraffin. The solution is intended for the prophylaxis of ophthalmia neonatorum in the newborn. The solution is marketed in two forms: capsules containing 6 minims of a 1 per cent solution, capsules containing 6 minims of a 2 per cent solution. Parke, Davis and Co., Detroit. (Jour. A. M. A., Nov. 24, 1923, p. 1789.)

PROPAGANDA FOR REFORM

The Menace of "Moonshine" Whisky.—The untoward results of overindulgence in whisky have usually been ascribed to its alcoholic content, although now and then ill-defined "by-products" of fermentation present in the distillate have been charged with a toxicity out of all proportion to the quantities ordinarily present. The indefinite "fusel oil" and furfurol were often designated as the pernicious ingredients. In properly made and suitably aged whiskies, such constituents could at most play only a minor part in the intoxication produced. While alcoholism is less prevalent today than it was a few years ago, its attendant and after effects on its victims are more serious. The impression is broadcast that this is due to the "moonshine" liquor which is being distributed. The danger from the presence of methyl alcohol in "moonshine" whisky is well-known. Its presence is explained by the use of denatured alcohol (which may contain methyl alcohol) in the preparation of "moonshine" whisky. However, the investigation of the federal authorities indicates that ordinarily methyl alcohol is not the pernicious constituent of illicit whisky, but instead the product has been found often to contain a high proportion of acetaldehyd. The "ranker" the liquor, the higher the aldehyd content. (Jour. A. M. A., Nov. 10, 1923, p. 1611.)

The Composition of Some Complexion Clays.—Next to nostrums sold for the alleged rejuvenation of the male, the most popular form of contemporary charlatanry lies in the exploitation of alleged beautifiers for the female. During the last year or two the cosmetic market has been glutted with a veritable avalanche of so-called complexion clays and face packs. The A. M. A. Chemical Laboratory has analyzed the following preparations of this class: "Terra-derma-lax," "Boncilla," "Domino Complexion Clay," "Mineralava," "Ryerson's Forty Minute Beauty Clay." The laboratory reports that each of the preparations was a bluish mass of the consistency of soft putty and resembled a mixture of clay and water. With one exception, no substance other than clay, water and perfume was found in the preparations. Domino Complexion Clay contained about five per cent of glycerin and about 0.2 per cent of a salicylate, probably sodium salicylate. The examination indicates that the clays analyzed are not high grade products, nor carefully purified before being used. (Jour. A. M. A., Nov. 10, 1923, p. 1624.)

Pregl's Solution.—It has been stated that Pregl's (isotonic) iodine solution is probably prepared by treating a solution of sodium carbonate with finely powdered iodine. When the iodine has dissolved, sodium chloride is added and the solution diluted to a definite volume. The product is stated to contain sodium ions, free iodine, iodide ions, hypiodite and iodate ions—this in addition to the carbonate and chloride. A proprietary brand of this solution is sold in Germany as "Presoid." All favorable reports of the therapeutic use of Pregl's solution have had their genesis from apparently biased sources. (Jour. A. M. A., Nov. 10, 1923, p. 1628.)

Iridinol.—The Council on Pharmacy and Chemistry reports that about fifteen years ago "Iridium (Medicinal)" was put on the market by the Platinum Co. of America, and the same company manufactured "Iridinol," which was marketed by the P. H. Potter Chemical Co. (now P. H. Potter and Sons, Inc.), New York. Both products were, at that time, claimed to contain iridium and were marketed for a high price with grossly misleading claims for the efficacy of iridium as a therapeutic agent. Iridium (Medicinal) seems to have been abandoned, but Iridinol, advertised by P. H. Potter and Sons, Inc., as an "ethical preparation" continues to be sold. In the earliest advertising Iridinol was claimed to be a "nontoxic preparation of iridium." At that time the A. M. A. Chemical Laboratory was unable to detect the presence of iridium, and it was concluded that no very large amounts of iridium could have been present. Regardless of the presence or absence of iridium, there is not the slightest evidence for the therapeutic value of this metal in the conditions for which it is recommended by the exploiters of Iridinol. In the present advertising for Iridinol no definite claim is made for the presence of iridium. Instead the agents merely imply its presence. Iridinol is recommended by the exploiters in anemia, rheumatism, specific blood diseases, diseases of the nose and throat, of stomach organs, liver and kidneys, of the nervous system, diseases of children and as a systemic alterative. In view of the long-continued activities of P. H. Potter and Sons, Inc., for the use of Iridinol, the Council authorized publication of a report for the information of physicians who may be importuned to use it. (Jour. A. M. A., Nov. 24, 1923, p. 1807.)

Whooping Cough Vaccine.—In a series of articles on biologic therapy prepared under the auspices of the Council on Pharmacy and Chemistry, W. C. Davison (The Journal, Jan. 22, 1921, p. 242) concluded a review of the use of pertussis bacillus vaccine thus: "In summing up the prolific and somewhat contradictory literature on this subject, it may be concluded that injections of Bordet-Gengou bacillus vaccines may have a slight though unreliable prophylactic effect, and that therapeutic inoculations are of practically no value. Further experiments are necessary to raise this procedure from the limbo of non-specific therapy." The Council on Pharmacy and Chemistry has accepted pertussis bacillus vaccine for New and Non-official Remedies, but states in regard to the usefulness of the product: "The evidence indicating that it is of value for either prevention or treatment is very questionable, and the reports are conflicting." (Jour. A. M. A., Nov. 24, 1923, p. 1809.)

PROCEEDINGS OF THE MINNESOTA ACADEMY OF MEDICINE

Meeting of November 14, 1923

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, November 14, 1923, at 8 o'clock. In the absence of both the president and vice president, Dr. Taylor called the meeting to order.

Dr. Taylor appointed Drs. Christison, Burch and McCloud a committee to draw up a suitable memorial for Dr. Warren A. Dennis, one of our past presidents, who had passed away since the last meeting of the Academy.

The minutes of the October meeting were read and approved.

The following case reports were given:

DR. OSCAR OWRE reported a case. (No history.)

DR. HENRY ULRICH reported a case and showed x-ray film of a Charcot hip.

Case seen in consultation with Dr. John Sessions. Young man 35 years old who began to limp and have some embarrassment of motion in left hip. Physical examination was negative so far as heart, lungs, etc., were concerned. X-ray of the hip showed a large tumor mass and a diagnosis of sarcoma was made. Neurological examination proved it to be a case of tabes with Charcot hip.

The rarity of Charcot hip is the only reason for bringing this case before you.

DR. GEO. DOUGLAS HEAD reported a case of pellagra.

The states of Wisconsin, Minnesota, North and South Dakota are considered as a non-pellagrous area, no well-authenticated cases having been reported. This is in strange contrast to many of the southern states, such as South Carolina, with its 1,000 cases, and Georgia with 2,000 cases, as reported in the 1910 U. S. census.

The following case which I have to report, is of interest, first, because it developed in South Dakota and is the first case to be reported from that area, and, second, because the patient had been deprived of meat proteins for about two years prior to the onset of the disease, and, third, because of the prompt recovery upon a meat diet and the use of cacodylate of soda intravenously.

Mrs. Emil B., 50 years, married, three children, living at Mellette, S. D., was referred to me by Drs. Kleger and McCauley, March 29, 1923, complaining of nervousness, soreness of mouth, diarrhoea, and a dirty brown rash over the forearms and hands. Her family history was negative. One sister dead of goiter. She had always been well until two years ago when she had a lot of teeth extracted, after which she began to feel tired. At Christmas time of 1922 she was very nervous and felt as if she would go to pieces. This feeling of exhaustion increased and in March of 1923 her mouth became sore and red and hurt her when she chewed food. About this time she began having seven or eight loose stools a day, and her rectum pained and burned. At this time also the skin on the forearms, halfway to the elbows, took on a dirty brown, scaly appearance. The rash gradually extended to the back of the hands and fingers. About two weeks after the rash appeared, the skin began to crack about the wrists. She had no headaches but was

confused in her mind and slow in her speech and thought. Her eyesight became blurred. She could not concentrate her mind upon whatever she might be doing. The diarrhea had stopped about two weeks before the examination was made. She had lost 25 pounds in weight. She stated that she had lived in the town of Mellette, S. D., for the last forty years, that she had in no way changed her diet or mode of living until after the teeth were removed two years before, when she stopped eating meat and had eaten soft foods, such as milk toast, cream of wheat, potatoes, carrots, cabbage, bread and butter, cream, cooked fruits, grapefruit, soft puddings, cake and pie.

The examination revealed a fairly well-nourished woman of rather stocky build, brown hair and eyes. Her color was a pasty white, somewhat suggestive of myxedema, or possibly early pernicious anemia. Pupils reacted to light and accommodation. Knee jerks were active. No incoordination. Her speech was slow and her mental responses sluggish. The mucous membrane of the lips and gums and inside of the mouth and the tongue was fire red, as shown in the color plate. There was a fine, whitish exudate, like that accompanying the spirillum of Vincent infection over the roof of the mouth and the jaws. This was easily wiped off. In places the mucous membrane hung down in folds. A remarkable crusty, dirty brown pigmentation and rash was present from about the middle of the forearms downward, extending over the backs of the hands and on the proximal parts of the fingers, as shown in the water color drawings. On the inside of the wrist the skin was cracked and red in the crevices. The rash had a rough, raised feel and a bran-like exudate could be rubbed off. The rest of the body was free of this skin rash, except a scaly, brownish area, the size of a dollar, over the dorsal surface of the right foot. There was a scaly, dark brown pigmentation and rash about the anus, and the mucous membrane of the rectum was red and angry looking. The rest of the physical examination was negative, except that there was some difference in the muscle strength in the extremities, the left arm and leg being stronger than the right. The urine findings were negative except a trace of albumen and an occasional narrow hyaline or granular cast. The blood findings showed a fairly high grade secondary anemia, hemoglobin 65 per cent, red cells 3,296,000 and leucocytes 6,250. Differential count: P. M. N. 70.0, small monos. 19.5, large monos. 7.0, trans. 0.5, eosinos. 2.5, myelocytes 0.5, no nucleated reds seen, no polychromatophilia, no basophilic stippling, no anisocytosis. Wassermann test negative. Blood pressure 132 systolic, 90 diastolic. Smears from the exudate upon the gums and roof of the mouth showed no spirilla of Vincent, but a long bacillus and diplococci.

A diagnosis of pellagra was made and the patient placed upon a liberal meat diet, with beef juice, and daily intravenous injections of freshly made cacodylate of soda, two to five grains to the dose. She improved steadily but slowly. She was dismissed from Abbott Hospital on May 21st, less than two months after her admission, the dermatitis and pigmentation gone, the mucous membranes free of redness and irritation, the weakness and exhaustion much improved, and her anemia corrected to a large degree. A letter from her in July reports no recurrence of the rash or other symptoms.

Dr. Joseph Goldberger, of the U. S. Public Health Serv-

ice, the recognized authority on pellagra in this country, and Dr. John Butler saw and examined the patient and the plates near the close of the treatment and pronounced the condition a case of true pellagra.

DISCUSSION

DR. CROSS: As Dr. Head has just said, the Northwest is not supposed to be a pellagrous area. There have been several well-authenticated cases of pellagra, however, in recent years which must have originated in the Northwest. Dr. Chas. Granger diagnosed such a case in Rochester about five years ago which was reported in full in the *Journal-Lancet*. The outcome of this case I do not remember, but I believe it recovered.

Two years ago I saw a woman in Red Wing, whose condition admitted of no question as to her being afflicted with pellagra. She was 52 years old and had lived her entire life in Idaho, with occasional visits to Minnesota. Up to four months before my examination of her she had been a strong, healthy woman, living in the pine country where her husband was foreman in a lumber mill. An operation four months before she was seen by me, for gallbladder trouble had resulted in a normal convalescence and return to Idaho. She did not recover her normal strength; in fact became weaker and more somnolent. When seen a few days before her death she was supposed to have uremia. It was difficult to get any reply although she was attentive and seemed to understand when questioned. There was no coma, no pain. The typical pigmentation of the hands and forearms was present, as were also large purpuric spots on the thighs, arms and chest. The history was typical. No autopsy was obtained.

Dr. Head has spoken of the possibility of other dietetic factors, as for instance a lack of protein. The case above stated, of course, during her convalescence was on a very limited diet for some time. The interesting thing to me is that she had never been south of our latitude.

DR. W. A. JONES: I recall a case that came under my observation two years ago. She came from Indianapolis, and was brought to the hospital suffering from protracted diarrhea, excoriation which covered the buttocks and surrounded the anus, discoloration of the skin which was fairly well marked and characteristic, and a peculiar mental state, a dementia, which I believe is quite common in pellagra. I gave her hypodermics of emetin, put her on a proper diet, and she made a recovery from the pellagra and the mental condition. One interesting point was that she was a morphinist before the pellagra developed. The emetin was given for its psychological effect as well as its effect upon the diarrhea.

DR. HEAD: I think that Dr. McCauley, of Aberdeen, made a tentative diagnosis of pellagra before this case was sent down, and our studies were really only confirmatory of the diagnosis which he had made.

I was very glad indeed that we were able to get the opinion of Dr. Goldberger, because he had stated while he was here that he was doubtful about our having pellagra in this part of the country, and one of the cases which he had come on here to see (a case from Duluth which Dr. Butler had seen) he had pronounced a non-pellagrous case. This case he did not hesitate in pronouncing pellagra after talk-

ing with the woman and seeing these plates and getting her history.

DR. MANN: Did Dr. Goldberger say anything about the cause of it?

DR. HEAD: Dr. Goldberger talked very freely about the research findings which had been carried on under his direction in the South, and he is firmly of the opinion that an alien protein, or the absence of certain proteins in the food, have considerable to do with the disease. He does not think that the older conception—abnormal products in the corn—are causal factors. He believes there are many proteins that may act in a causative way to produce it.

DR. PAUL COOK: I just want to say that there is a typical case of pellagra in the Aberdeen Veterans' Hospital, in St. Paul; at least the case was there three or four weeks ago. This case is of a severe pellagra-typhosus type, with gauntlet-like dermatitis.

DR. E. L. GARDNER read a paper entitled "Hypothyroidism, with Special Reference to Minor Thyroid Deficiencies."

DISCUSSION

DR. L. C. BACON: This excellent paper is so exhaustive and covers so completely the subject that the only discussion which seems proper is to speak of a case of myxedema, which I have been able to follow for over thirty years, because it emphasizes some of the points of the paper.

I saw her first during the early '90's; she was 37 years of age, with the history that she had borne five children and at 33 years of age she passed the menopause. Her husband told me that earlier in life she had been of a happy disposition but when the menopause came she became "dull and foolish." She was a large woman with puffed face, eyelids and lips especially so. The skin was pitted, lips and gums bluish, hair was dry, thin and short, and her expression and actions denoted stupidity and lack of vigor. Constipation was obstinate and she complained of a constant dull headache.

About this time I had been reading, in the London Lancet, the report of the British Commission to investigate myxedema, and I considered this a case of the disease in question. I obtained fresh sheep's thyroids from South St. Paul and had her eat them. The improvement was immediate and marked, and in about four months there was a restoration of the menstrual function, which continued until the late forties. She is a little past seventy now and is happy and hearty for her age.

Some months after I first saw her, thyroid extract came on the market and she has used it in tablet form since. During the first few years of the use of the thyroid extract, when she would reach a point of feeling very well, she would discontinue the remedy and would soon become very constipated and her dull headache would reappear, or if she were taking the tablets and the headache and constipation appeared it would be a warning that that particular lot of tablets was inert and fresh would be obtained. Sharp headaches with rapid heart action would warn her that she was taking too much of the extract and the amount would be reduced. After she understood that she must accept a life sentence and took the extract regularly she remained in good condition and she has enjoyed a happy, cheerful life. She finds that one-half of a 5-grain tablet twice a week about meets her needs.

About five or six years ago I did a cholecystectomy on this patient and she did very well. The wound healed promptly, but about two weeks after the operation the scar became red and infected and suppuration occurred. The thyroid had been overlooked during the period, but when exhibited again, healing was prompt and satisfactory.

DR. H. L. ULRICH: I think Dr. Gardner has shown us very beautifully the variation of the potency of the commercial extracts we have on the market. The basal metabolic rate determinations show the importance of this point, that one must have active extracts to get therapeutic results. There are a good many clinicians who scout these mild types of hypo-thyroid states. Those of us who are on the lookout for these are convinced that there is such a condition, particularly after the fourth decade of life. In regard to the heart: there is no question in my mind that there is such a thing as a myxedema heart, and that these hearts are going about with the diagnoses of myocarditis, valvulitis, etc., whereas there are purely functional changes in the hearts. In hypothyroidism the general muscular tone of the body is depressed and so likewise the tone of the heart is depressed. If you examine these patients with the x-ray you find their hearts hang way down in the chest like a drop-heart. We have just had such a case in the hospital with all the signs of hypothyroidism. There was a blocking in the Q. R. S. complex in the electrocardiogram and this patient had been diagnosed a myocarditis. Under medication of thyroid the insufficiency of the heart has disappeared, she has regained a normal electrocardiogram and all the other symptoms have disappeared.

DR. W. P. LARSON gave a paper entitled "The Problem of Wetting Bacteria." There was no discussion of this paper. The meeting adjourned.

JOHN E. HYNES,
Secretary.

TRANSACTIONS OF THE MINNEAPOLIS SURGICAL SOCIETY

Stated meeting held November 8, 1923, the President, J. M. Hayes, in the chair.

The guest of honor, Dr. C. H. Mayo, favored the Society with a few remarks before departing to take part in another program.

DR. J. F. HEDENSTROM presented a case of splenic anemia which had been operated by Dr. Wilcox.

DISCUSSION

DR. A. W. WILCOX: I think our pediatric division at the General Hospital is to be congratulated upon the complete records of this case of splenic anemia which has been so ably presented by Dr. Hedenstrom. The diagnosis is the result of minute study and keen interest in the work.

The surgical aspects of this case are entirely technical. The diagnosis was made before the patient was transferred to our surgical division, although we had an opportunity to observe the child for some time for operation. One who has observed this child for some time before operation and since operation can hardly believe it is the same

patient, the clinical improvement has been so marked following splenectomy.

In surgery of the spleen, with few exceptions, splenectomy is the only operation done. Occasionally abscesses have been opened or tumors removed but the essential surgery is confined to splenectomy.

Regarding the operation the approach to the spleen can be most practically made by incision through a left rectus incision, although other incisions are recommended, such as transverse incision or incision parallel to the costal margin.

In this particular instance a left rectus incision was selected and excellent exposure of the spleen was obtained. On opening the abdomen some free fluid was found. This was interesting on account of the fact that the child had several intraperitoneal transfusions. The omentum presented a large hematoma in the upper left quadrant, and in addition to this several adhesions between the coils of the small intestines and rather marked fibrous adhesions between one of the coils of the intestine and bladder. The diaphragmatic surface of the spleen was rather firmly fixed to the diaphragm. These adhesions between the spleen and diaphragm were separated and the spleen brought downward, the gastro-splenic omentum on its anterior surface then divided. Although this was easily done there were some places where the adhesions which were rather firm had to be divided by scissors. The spleen was then rolled toward the midline. This gave an opportunity to dissect away the peritoneal adhesions existing between the spleen and left kidney, and also by dissecting close to the splenic tissue the splenic vein and artery came into view and also the tail of the pancreas. Further dissection of these tissues brought the pedicle with the vessels into plain view. The spleen was now quite mobile and the pedicle ligated in two portions and removed.

Another interesting point was the fact that the essential peritoneal covering of the spleen was easily removed from the splenic tissue proper so that when the spleen was removed it looked like a freshly prepared anatomical specimen. Its weight was 160 grams. The histological and pathological reports have not been finished.

In this particular case the technic proved very simple. The essential factors to recapitulate were: (1) complete freeing of the diaphragmatic surfaces; (2) division of the gastrosplenic omentum; (3) the dissection of the posterior surface without injuring the pancreas and exposing the blood vessels.

The child's present appearance, which I thought it would be interesting for you to observe, speaks for the great improvement and its general condition since the operation.

REPORT OF THE TRI-STATE MEETING

DR. R. E. FARR: As all of you know who have read the program of the Tri-State meeting, which was just held at Des Moines, this was one of the most successful adventures of this kind ever carried out. Almost every disease that the practitioner comes in contact with was discussed and brought up to date by experts. It was the greatest galaxy of stars I have ever seen on a program. The large

auditorium was usually well filled by seven o'clock in the morning and all four evenings were taken up. I talked to this audience at the end of the thirteenth hour of work on the first day and there was still a large crowd in attendance. It means that men from all over this part of the country are hungry for post-graduate work.

The meeting was very well handled and as a rule the speakers were held strictly to their allotted time. I might illustrate its excellence by referring to the clinic of Joslin given upon diabetes. About fifty patients with diabetes were sitting upon the stage. Dr. Joslin illustrated his talk and drove home the points by quizzing the various patients and showing how well trained they were in the handling of their own disease. To illustrate the knowledge of the layman who has diabetes compared with that of the average doctor Dr. Joslin asked a doctor in the audience how much sugar an apple which he held in his hand contained. The doctor estimated the amount at one gram. He then asked a little girl of seven the same question. She estimated the amount at fifteen grams. The apple was weighed and it was found to contain sixteen grams of sugar.

The doctor asked another child to step forward and demonstrate the method of examining the urine. He illustrated practically every phase of the disease by the case of some patient who was present.

There seems to be no question but what the medical profession is demanding this sort of entertainment and yet I cannot resist the feeling that there is a possibility of such meetings interfering greatly with the program of our State and County Medical Associations. Dr. Evans of La Crosse told me that the same territory which sent but three men to the Wisconsin State Medical meeting contributed at least twenty to the Tri-State meeting. I think it is well for all of us to have in mind the ultimate effect of this sort of thing upon our national associations.

There are, as you know, two methods of arranging programs. One consists in gathering together specialists from different parts of the country who present their subjects in an extremely attractive manner. The other is the plan carried out by our State and County Medical Societies in which the local members furnish the program almost entirely. Now, provided such programs as that furnished at the Des Moines meeting are presented with sufficient frequency, what effect will it have upon our State and County meetings? In the last meeting of our County Society the attendance was extremely slim. One viewpoint of the general practitioner may be illustrated by the statement made by a man from northern Wisconsin who attended the Tri-State meeting. He said that he considered that he had made a great mistake in spending his time and money attending the State Medical meeting at Milwaukee this year when with very little greater expenditure he could have attended the Des Moines meeting. His idea was that he had practically wasted the time and money spent attending the State Medical Association.

In Ohio they have a plan known as the Dayton plan, which has been followed out for a number of years. The members of that district pay \$10 per year. The lecturers are paid at the rate of \$100 a day and expenses. Six fifty-minute lectures are given for a period of four days. I appeared on this program in October of this year and

found that the Association now numbers two hundred and fifty men and that every man was in his place throughout the four days.

I feel that we should be extremely careful to guard the interests of our County and State Medical Societies which are, as you know, the component parts of our national organization and that every effort should be made to develop as many of the men in the profession as possible. Should the pendulum swing too far the other way I doubt if it would bring the greatest good to the greatest number, which is, of course, what we desire.

REPORTS FROM THE RECENT CLINICAL CONGRESS OF SURGEONS HELD IN CHICAGO

DR. H. B. SWEETSER: If I had thought of bringing some new light to you, I would probably have paid more attention to the stage than I did. The first two days the clinical congress of surgeons was confined to a consideration of hospital matters, and that to me was of very great interest. Here a great many surgeons from all over the country had assembled for the purpose of getting some light on surgical matters. But although they were having clinics every place they spent practically these first two days in this general meeting room in the hospital conference. The auditorium there must have contained probably fifteen hundred people, I think, and it was crowded from early in the morning until they closed at six o'clock. Their discussions were on ways of improving hospital methods. Not only were the men there but they stayed there from morning until night. Not only that, but they discussed all the various activities of the hospital; they discussed members of the staff; nursing problems; interne problems; equipment for the hospital; x-ray; different kinds of laboratories, etc. The discussion was general. They had conferences, and one man presented something and then it would be discussed from all parts of the hall by men from all parts of the country. They all seemed to talk intelligently; they were all interested.

Some of the things they discussed were whether they would have a single charge for laboratory tests or whether they would charge for each test; and there was a division of opinion there. They discussed tonsil cases. That was a long discussion: whether the children for tonsillectomy should be brought in the night before or whether they should be brought in that morning and then operated upon. There was a great difference of opinion about that. Some thought that they should be brought in in the morning. Some said that would so disrupt the families that it could not be done, and it was not necessary. Then they read the standings that were given to the various hospitals throughout the country. In 1918 only 12 or 13 per cent came up to the required standard; in 1923, 86.1 per cent. You see the hospitals have met this requirement for standardization with a great deal of enthusiasm.

The last day they had a model staff meeting. There was a good deal said about staffs: how the hospitals should treat them, etc. The Evanston Hospital put on what they called a model staff meeting. The members came out and spread themselves around the stage and the presiding officer announced: "This meeting probably will be a little more harmonious than it ordinarily would be if we were

not on exhibition." It really was very much more harmonious than any staff meeting that I have ever attended. He called upon somebody to make a report; the report was made and it was adopted without any discussion. One man reported on the deaths and among them was one very badly-treated case. It was criticized and they came to the conclusion that he should be informed by the secretary that he would have to do better. Just what method they had of making it better I don't know.

They divided into business meetings and into scientific meetings. The business meetings were held at the University Club in Evanston; the scientific meetings were held at the hospital. The Board of Trustees were not invited to their business meetings, apparently; and they all recommended things for the consideration of the Board of Trustees.

Every year they have a social meeting; I thought that was a good idea. They invite their wives and they have a dinner and they have a very pleasant time at that social meeting. There are certain dues: the older men pay \$25 a year; the junior men pay \$20 a year. That money goes for paying for the dinners and also for maintaining the library. They have thirty current journals in the hospital. I think that is a mighty fine idea. The social meeting gets the doctors together in that way with their families, and the library provides proper medical literature for the internes and for the staff.

DR. O. W. YOERG: Dr. Kanel gave a very interesting and instructive clinic on surgery of the hand.

The first operation was performed on a man who some time previous had had a severe infection involving the index finger and with a resulting loss of the power of flexion of the finger. The operation was performed under local anesthesia. On incision it was found that a good deal of the tendon had sloughed out and new tendon was made by making incisions laterally through the scar tissue, conserving a band of scar tissue, which were allowed to remain attached to the distal and proximal ends to the tendon remaining. A flap of fat was loosened and brought under this constructed tendon. The scar tissue tendon was then shortened, so that the finger could be flexed to almost right angles at the metacarpophalangeal joint and the distal joints were held slightly flexed. This overcorrection he says was necessary to obtain full function. The wound was closed and the hand placed on a splint.

Dr. Kanel told of making new tendons with twisted strands of silk, interposing between the ends of the missing tendon, and adding to the strands of silk any scar tissue available. He laid stress on early motion in these cases, beginning in three or four days after operation and gradually increasing in amount. This early motion was demonstrated to him by a patient on whom he had done a similar operation, the making of a tendon for a thumb. She had been sent home with instructions not to use the thumb for at least six weeks, but on returning to see him six or eight weeks later perfect function had been restored. She stated that she had not followed his instruction and had used her hand playing a piano.

A second operation was done for suturing of a divided median nerve.

Cases showing late results of tendon making were shown and methods of tendon suture were outlined. A case of a boy who had been some time ago operated upon for webbed fingers was presented. The operation performed on this boy had been done by making a flap of the palmar surface of the web and bringing it back between the fingers and suturing the flap on the back of the hand.

Doing skin grafts on the exposed sides of the fingers. Dr. Kanavel told of his method of operating on cases for palmar infections, in which the flexor tendons were bound down, so that the fingers could not be flexed. He removes all the scar and a good deal of skin from palm of hand, loosens up the tendons from the underlying structures, brings the hand back and places it in a pocket, made by two horizontal incisions on the back. A separate flap of fat is made from the loosened skin of the back and this flap is slid underneath the tendons and the skin over them. The hand is kept sutured to this flap, which is attached above and below, and in about two and one-half weeks the flap is cut away from its upper and lower attachments and finally trimmed to fit the hand. Motion is started early.

DR. A. F. BRATRUD: Dr. Lespinasse at Wesley Hospital gave a demonstration of the results of the removal and transplantation of glands in chickens. It was very interesting from a scientific point of view only. In one case, there were two chickens. One had the typical appearance of an ordinary hen and the other had the typical appearance of a rooster. He made the statement that these two chickens were sisters at birth but that, in the one which appeared to be a rooster, the ovary had been removed and four testicles from other roosters had been transplanted shortly after hatching. The head and plumage was that of a rooster as well as the shape of the body. It even had fairly well developed spurs.

In another series of chickens he had been using roosters only for his experiments. Here he started by removing testicles—one-eighth at a time, until he had removed seven-eighths of the testicles. As the greater amounts were removed, the birds gradually changed in their physical development so that they approached to the shape of the head and body of the hen, i. e., the head approached the triangular shape head which is characteristic of the hen, and the bulky breast of the rooster gradually became smaller as is characteristic of the hen. There was very little change in the plumage in these cases.

From a practical point of view, I do not think it yet amounts to much but that it may have a future.

DR. S. R. MAXEINER: I am going to give you just the notes as I took them from Strauss's clinic. His first case was one of pyloric stenosis. He reported that he had done 384 operations for congenital pyloric stenosis with eight deaths. I do not know of any place elsewhere the same record has been made. He made several interesting statements which I jotted down. The first was that he was repeatedly called to the infants' home where he was on the staff, to operate a case of pyloric stenosis that had developed within the first week; but those were never true cases of pyloric stenosis. He said that in the history of his 384 cases there was not one exception where there was an

actual pyloric stenosis which developed before the tenth day. The average was between the tenth and the fourteenth day, and frequently the symptoms did not develop before the third week.

Pyloric stenosis, he states, is due to hypertrophy of the pyloric muscle. For instance, he compares it to the arm of the blacksmith who, constantly swinging a hammer, develops an enormous biceps. The pyloric muscle in these infants is constantly in a rhythmic, spasmodic contraction, and due to this rhythmic contraction it becomes extremely hypertrophied. That is what he calls a real, true hypertrophic stenosis.

He speaks of what is called the water test. These babies are placed upon the table, stripped, and the abdomen is inspected. Frequently in the normal child peristaltic waves are noticed in the stomach, but these are small rhythmic contractions. In the real pyloric stenosis case he gives a small amount of water from a bottle, and there immediately occurs a peristaltic contraction in the stomach; and because of the spasm of the pylorus, these waves are what he calls big waves, and are absolutely characteristic of these pyloric conditions. Then he follows this by a small amount of bismuth which is put into the stomach. The baby is turned from side to side, and then the stomach is emptied. There is no bismuth left in the stomach except what coats the sides. Then under the fluoroscope he demonstrates conclusively these same large waves that he sees through the abdominal wall.

He states that the amount of obstruction varies from 20 to 100 per cent. In cases of 100 per cent the procedure is obvious. Cases where there is less than 50 per cent retention in the stomach produce a normal stool; and as a result he does not believe that the stool is of any particular value in these cases. You may get a starvation stool in anything over 50 per cent retention. In cases where there is more than a 50 per cent retention, he says to operate immediately. He states that the cardinal points in diagnosis are this water test, with the visible peristaltic waves, projectile vomiting, and the interval of ten to fourteen days before the onset of symptoms. The palpation of the tumor is of no importance whatever. Emaciation depends entirely on the length of time and the amount of obstruction. All of his bad cases are preceded by a transfusion into the longitudinal sinus of 75 c.c. of blood; and frequently he gives 5 per cent glucose or salt solution also into the longitudinal sinus. When the operation is done on very bad cases, or the children show evidence of shock—that is, not exactly shock, but show the effect of the operation—he follows with another transfusion of 75 c.c. of blood.

The technic of his operation for pyloric stenosis is described in the system of surgery by Ochsner.

DR. JAMES A. JOHNSON: One of the interesting things I observed in A. J. Ochsner's clinic, during the meeting of the Clinical Congress in Chicago, was the experimental work done by Dr. Nuzum on the causation of cancer. Dr. Nuzum had isolated an anerobic organism from a human breast cancer. This organism he had cultured and injected repeatedly into the breasts of ten dogs. Finally one of the older dogs developed a cancer of the breast

which progressed to a fatal termination—the post-mortem showing extensive metastases into practically every organ. Dr. Nuzum had been quite enthusiastic about discovering the cause of cancer; and Dr. A. J. Ochsner, in one of his discussions of the subject, stated that he believed Dr. Nuzum's organism was the cause of cancer.

However, with further experimentation Dr. Nuzum has not been able to isolate his organism from the cancer, which he produced, and transplant it to other animals.

Dr. Nuzum now does not believe that the organism was the direct cause of the cancer, but that it was in all probability due to the constant irritation both mechanical and bacterial which he produced by the constant injection into the breast.

Dr. S. H. Baxter read a paper entitled, "Retroperitoneal Tumor." (See page 42.)

At the conclusion of the program all the members of the Society stood in silent tribute to the memory of Dr. Warren A. Dennis, of St. Paul, news of whose death had just been received.

THE CAUSE OF BOTHRIOCEPHALUS ANEMIA:

Russel L. Haden (Amer. Jour. Med. Sc.). The broad tapeworm is most commonly encountered in the Baltic provinces of Russia, the Scandinavian peninsula and certain parts of Switzerland, and is the most common tapeworm of China and Japan. The intermediate host is fish, and man is infected by eating raw or improperly cooked fish containing the cysticercus stage of the parasite. The case reports in the United States have not been very numerous, but the paucity may be partially due to lack of careful observation.

Unlike the secondary anaemia occurring in other parasitic infections, the picture of anaemic in bothriocephalus infections cannot be distinguished clinically from true idiopathic pernicious anaemia. The similarity in the clinical picture has excited interest among research workers, in the hope that a solution of the cause of anemia in bothriocephalus infections may throw some light on the cause of pernicious anemia. Attempts to reproduce the anemia with extracts from normal worm have not been successful. Schaumann and Tallquist found that by feeding or injecting subcutaneously dogs with worms which had been subjected to tryptic digestion, an anemia could be produced. Faust and Tallquist noted that the worms recovered from patients having anemia show a great deal of loss of substance—sometimes as much as 60 per cent per unit of length, as compared with the normal worm. The cause of this disintegration is not clear.

The author reports a case in which infestation had apparently occurred six years previous to coming to the United States from Finland, as he had passed segments of tapeworm at intervals for at least two years. The patient had developed rather sudden symptoms of anemia, and on recovery the worm was found with its segments densely intertwined and undergoing disintegration. Haden believes that this is corroborative of Tallquist's observation that worms recovered from patients with anemia show loss of substance, and that the onset of symptoms is due to the death of the worm and the anaemia due to the absorption of decomposition products. The condition of the patient improved promptly after the passage of the worm, and after sixteen days the red blood count had advanced from 2,000,000 to 3,673,000, and ova could no longer be found in the stools.

F. J. HIRSCHBOECK.

MECHANISM OF PRODUCTION OF BREATH SOUNDS: P. Martini (Arch. Int. Med., September 15, 1923). Just as on percussing the air-containing lung the specific sounds of the two naturally dependent and connected systems (chest wall and lung) determine the percussion sound, so the breath sound over the air-containing lung is composed of two specific sounds: that of the bronchial system and that of the air-containing lung tissue.

Only the sound of the chest is heard on percussion over a massively infiltrated lung, the lung itself remaining mute. The specific sound of the infiltrated lung has no part in the bronchial breathing heard over it. Pathologic bronchial breathing is the expression of correctly transmitted vibrations. During the respiration the air in the bronchi is caused to vibrate in the form of split and cut sounds. The glottis is not necessary for this purpose. The importance of the laws of forced vibrations in the problem of auscultation is stressed.

THE RELATION OF RIGHT-SIDED ABDOMINAL PAIN TO RIGHT-SIDED DISEASE: R. C. Coffey (Jour. of the Amer. Med. Assn., September 15, 1923). Right-sided abdominal pain is often due to other causes than pathological conditions in the gall-bladder, head of the pancreas, right kidney, appendix, and right ovary.

A study of a class of cases described by Wilms, Klose and Lichty has convinced the author that a large percentage of the cases of chronic right-sided abdominal pain are the result of defective fixation of the ascending colon. This defective fixation is due to four degrees of defective fusion of the primitive mesentery of the colon in fetal life. The

second degree is where the colon has rotated as far as the kidney and has become attached to its anterior surface, leaving the ascending colon and cecum mobile. This group creates most of the trouble.

"Pain resulting from defective peritoneal fusion is directly produced in two ways: (1) by distention of a mobile prolapsed cecum, and (2) by traction on acquired membranes or bands which help to carry the weight of the organs below."

One case is described in detail and a description by Waugh is given. The characteristic features are (1) appearance of an absolutely irregular right-sided pain at the age of 20 or 25, (2) mild indigestion not affected by diet, bad habits, or unsuitable environment, (3) loss of weight and profound lassitude, and (4) general tissue wasting and degeneration in the later stages.

The author cites one case in which the following chain of pathological changes developed as a result of nonfixation of the right colon:

1. Nonfixation of the cecum and ascending colon.
2. High fixation of the appendix and its mesentery well up under the liver.
3. Fixation of the hepatic flexure to the front surface of the kidney, with acquired membranous development to strengthen the supports.
4. Acquired membranes attending from the parietal peritoneum across to the mobile colon.
5. Acquired membranes along the under surface of the first part of the transverse mesocolon for the extra support of this part of the colon.
6. One band extending along the omentum from the colon to the under surface of the gall-bladder.
7. Another extending from the colon across the duodenum making extra fixation.
8. A midline ptosis probably due to dilatation of the stomach, secondary to dilatation of the duodenum, which was produced by duodenal arteriomesenteric ileus.

"Forced feeding and fattening will relieve a certain number of these patients of their pain, but painful conditions of the right side of the abdomen are usually best treated by surgical measures, which usually consist of shortening the mesentery of the cecum and ascending colon and fixing it to the posterior lateral parietal peritoneum by interrupted sutures without actually sewing the intestinal wall. At the hepatic flexure the line of interrupted sutures is gradually brought forward on the lateral parietal peritoneum, picking up the mesentery of the colon, attaching it to the front wall until the beginning of the omentum is reached, when the omentum is attached to the anterior abdominal wall over as far as the midline and sometimes 3 or 4 inches beyond. If the cecum is extremely dilated, plication may be performed."

"At present I do not hesitate to operate for long continued annoying right sided pain with the positive assurance that in the majority of all cases I shall be able to relieve the pain whether it is due to organic lesions or to inorganic disease accompanying defective peritoneal fusion."

UBER SCHWERE FORMEN VON ANAMIE BEI SEPTISCHEN ERKRANKUNGEN: Max Frank (Archiv für Kinderheilkunde, July 21, 1923). The author presents three cases of severe secondary anemia in infants.

In two of these positive blood cultures were present. One, a urinary infection, had bacilli coli in the blood stream. The other was a general infection resulting from multiple skin abscesses, and showed staphylococci in the organs at postmortem.

The third case was a generalized infection following a bronchitis in a poorly nourished infant. No positive blood or organ culture was demonstrated in this case.

All three patients showed a severe, rapidly developing anemia, with a color index less than one. Anisocytosis, poikilocytosis and polychromatophilia were present in all cases.

In those in whom positive cultures were found, the nucleated red blood corpuscles were diminished, the leucocyte counts were only slightly elevated, and the platelet counts were definitely reduced, as low as 7,400 per cu. mm.

On the other hand, in the third case, where a pyemia rather than a septicemia was present, the leucocyte count was markedly elevated, the nucleated red blood cells were numerous and the platelets were within normal limits. A few neutrophilic myelocytes and even myoblasts were seen.

The bone marrow in the cases of septicemia showed a definite diminution in the number of P.M.N. neutrophiles and giant cells. These elements of the bone marrow were normal in the case of pyemia.

Frank believes that in the cases of septicemia there is a hypoplasia of the bone marrow due to the action of bacterial toxins. This condition is not present in pyemias where one sees a normally reacting bone marrow.

H. S. LIPPMAN.

THE IODIN TREATMENT OF GOITER IN OLDER GIRLS: W. Silberschmidt (Schweizerische Medizinische Wochensh, Basel, July 1923). Silberschmidt reports the result of the systematic administration of iodine tablets to girls ranging from 15 to 22 years of age. From two years' observation he concludes that this treatment is borne well, is harmless, and that many pronounced goiters retrogress. The beneficial results apparently are more marked in individuals having soft, than in those having hard goiters. He states also, that the iodine treatment is undoubtedly more promising for children than for adults. Goiters having connective tissue infiltration are not likely to show much benefit from the administration of iodine tablets or iodized salt.

BOOK REVIEWS

BOOKS RECEIVED FOR REVIEW

THE DIETARY OF HEALTH AND DISEASE. Gertrude I. Thomas, Instructor in Dietetics, University of Minnesota. 210 pages. Illustrated. Philadelphia and New York: Lea & Febiger, 1923. Cloth, \$2.25.

MODERN ASPECTS OF THE CIRCULATION IN HEALTH AND DISEASE. Carl J. Wiggers, M.D., Professor of Physiology in the School of Medicine, Western Reserve University, Cleveland. 2d edition, revised. 662 pages. Illustrated with 204 engravings. Philadelphia and New York: Lea & Febiger, 1923. Cloth, \$7.50.

A MANUAL OF PROCTOLOGY. T. Chittenden Hill, Ph.B., M.D., F.R.C.S., Instructor of Proctology, Harvard Graduate School of Medicine; Surgeon to Rectal Department, Boston Dispensary; Ex-President American Proctologic Society. 279 pages. Illustrated with 84 engravings. Philadelphia and New York: Lea & Febiger, 1923. Cloth, \$3.25.

DISEASES OF THE SKIN. Frank Crozer Knowles, M.D., Professor of Dermatology, Jefferson Medical College, Lieutenant-Colonel Medical Reserve Corps, U. S. A.; Dermatologist of the Philadelphia General, the Presbyterian, the Children's and the Babies' Hospitals; Chief of Clinic, Dermatological Department, Pennsylvania Hospital, etc. 2d edition, revised. 595 pages. 229 illustrations and 14 plates. Philadelphia and New York: Lea & Febiger, 1923. Cloth, \$6.50.

THE TREATMENT OF DIABETES MELLITUS. Elliott P. Joslin, M.D. (Harvard), M.A. (Yale); Clinical Professor of Medicine, Harvard Medical School; Consulting Physician, Boston City Hospital; Physician to New England Deaconess Hospital. 3d edition, revised and enlarged. 784 pages. Illustrated. Philadelphia & New York: Lea & Febiger, 1923. Cloth, \$8.00.

RHUS DERMATITIS (Poison Ivy): Its Pathology and Chemotherapy. James B. McNair, University of Chicago. 298 pages. 15 illustrations. 3 plates. University of Chicago Press, 1923.

DIATHERMY AND ITS APPLICATION TO PNEUMONIA. Harry Eaton Stewart, M.D., attending specialist in physio-

therapy, U. S. Marine Hospitals, New York; consultant in physiotherapy, U. S. V. B. Hospital, New Haven, Conn.; director New Haven School of Physiotherapy; formerly assistant director, Section of Physiotherapy, Office of the Surgeon General, U. S. Army, and Supervisor of Physiotherapy, Bureau of U. S. Public Health Service, Washington, D. C. 210 pages. New York: Paul B. Hoeber, Inc., 1923. Cloth, \$3.00.

THE TREATMENT OF DIABETES MELLITUS WITH OBSERVATIONS BASED UPON THREE THOUSAND CASES. Elliott P. Joslin, M.D. (Harvard), M.A. (Yale). Third edition, enlarged, revised and rewritten. Lea & Febiger. Price, \$8.00.

This edition contains many new sections. The sections of insulin, pathology, respiratory metabolism, levulose, duodenal ulcer and diabetes of twenty years' standing have appeared for the first time. Marsh and Newburgh methods of treating diabetes are also very clearly and impartially discussed. Much room is given to the discussion of the modern conceptions of acidosis. While the second edition contains numerous tables, the third has many additional ones. Among the more important are the tables of diabetic and non-diabetic foods by Dr. E. M. Bailey and the tables for predicting the metabolism by Harris and Benedict. Numerous parts here and there through the entire book have been either supplemented or somewhat changed due to the introduction of insulin treatment and the acquisition of a more exact knowledge based on numerous experiments and observations during the last decade. The section on surgery has been entirely rewritten.

The work has no equal. Its growth has been phenomenal. Six years ago the author based his treatment on thirteen hundred cases. His treatment of diabetes now is based on three thousand cases. "To Banting and Best and the Toronto Group of Insulin Workers" is dedicated this masterly production. This same spirit which prompted the author to dedicate his work to the above men characterizes also the impartial discussion of any contribution, regardless of how insignificant its source may have been, to the better understanding of diabetes. No one attempting to treat diabetes can be without this work.

THE CLINICAL SIGNIFICANCE OF PAIN IN THE AREA SUPPLIED BY THE FIFTH CRANIAL NERVE*

HARRY L. PARKER, M.D.

Section on Neurology, Mayo Clinic
Rochester, Minnesota

It is very difficult to estimate pain as a part of a patient's complaint, since it is relative and varies with sex, race and temperament. Pain cannot be seen, felt, nor measured directly by the examining physician; he has only the patient's word, and his reaction to stimuli. Pain is usually regarded as an index of existing disease, and its cause is diligently sought so that cure may be effected. The ease with which this objective is reached often depends on the associated signs and symptoms discernible at the time. If these companion symptoms are lacking, the difficulty of interpreting pain on its own merits becomes exceedingly great, more especially if it is inconstant in degree, type and location, and corresponds to no familiar sign of disease. When pain assumes certain characteristics and occupies a certain location, in a combination which is familiar, having occurred in patients throughout the ages, it may be classified as a distinct disease entity, even though its cause remains completely unknown. For example, there is no general agreement with regard to the pathologic lesion of paroxysmal trigeminal neuralgia, but its manifestations are so definite and invariable from patient to patient and from time to time, that without clinical signs or objective findings, a diagnosis is made with comparative ease. The patient's story alone is sufficient to make the diagnosis, and this story remains the same, irrespective of sex, race or temperament. If, however, there is pain in the area usually affected by paroxysmal, trigeminal neuralgia, but not of the type characteristic of that disease, the difficulty of diagnosis is

great, since there may be no objective findings to indicate the cause or nature of the pain. Paroxysmal trigeminal neuralgia is included in our classification of disease, since it does not vary in its manifestations, even though they consist merely of pain. However, any unusual pang, unsupported by clinical findings, may not have a name under which it may rest complacently in a pigeon-hole of our classification of disease.

With the more recent means of alleviating permanently the suffering caused by paroxysmal trigeminal neuralgia, physicians are eager to separate from the vast multitude of patients with hitherto unclassified pains, aches, and algias, those having a disease which they can cure. This is comparatively easy, since the manifestations of paroxysmal trigeminal neuralgia are well known, and it has been satisfactorily settled that there is only one true type of the disease for which there is appropriate and satisfactory treatment. It has also been established that the application of this treatment to any disease that is not true paroxysmal trigeminal neuralgia brings disaster, the final state being worse than the original disease.

INDEFINITE NEURALGIAS

The question arises: What constitutes the classification, etiology and treatment of all the other pains and aches in the fifth nerve area wherein all obvious causes have been carefully eliminated, and what are these pains? The use of the word "neuralgia" means nothing more than that there is pain in the area supplied by a certain nerve, and like charity this name covers a multitude of sins of ignorance.

In a large clinic a certain number of patients complaining of pain in the fifth nerve area are referred to the neurologist, after the internist, dentist, ophthalmologist and rhinologist are satisfied that they cannot find the cause of the pain. On the neurologist, therefore, is thrown the responsibility of claiming that the pain occurs in a disease in his own field of study. The responsibility in such cases becomes heavier when a routine neurologic

*Read before the Minnesota State Medical Association, October 10-12, 1923, St. Paul.

examination reveals no disturbed function. I shall discuss here only these cases in which pain is the sole complaint, with few or no clinical findings, and not attempt to go into all the causes of pain in the area supplied by the fifth nerve.

LESIONS AFFECTING THE FIFTH NERVE

TABLE 1

PAIN IN THE FIFTH NERVE AREA DUE TO INVOLVEMENT OF THE NERVE AND ITS CENTRAL CONNECTIONS

Peripheral lesions: (1) trauma, scar tissue formation and pressure by bone fragments, (2) inflammation of nerve endings due to local septic processes (peripheral neuritis), and (3) chronic paroxysmal trigeminal neuralgia (?).

Lesions involving nerve trunks: (1) trauma to bony canals, or hemorrhage around nerve trunk and scar formation, (2) tumor formation pressing on nerve (nasopharyngeal malignancy), and (3) local septic processes (interstitial or parenchymatous neuritis).

Lesions of posterior root ganglia or posterior roots: (1) ganglionitis, posterior poliomyelitis or herpes trigeminus, (2) tumors arising from ganglion envelopes or arising elsewhere and compressing it, (3) local meningitis, syphilitic or nonspecific epidemic encephalitis, and (4) tabes dorsalis.

Lesions of the brain stem: (1) tumor in the pons, (2) thrombosis or hemorrhage of the posterior inferior cerebellar artery, (3) multiple sclerosis, and (4) arteriosclerotic softening (?).

Lesions in the optic thalamus.

Lesions in higher associative brain centers: (1) hysteria—"psychalgia."

Migraine.

Considered anatomically, the fifth nerve may be affected at the periphery, along its extracranial course, or inside the skull. It may be damaged at the ganglion, in the posterior root, or at the termination of the root in the brain stem. It is worth while to review the more familiar lesions affecting the nerve, including only those that involve the nerve itself or its branches, omitting the more numerous cases of pain due to disease of organs supplied by this nerve, or pain referred along the course of the nerve from diseased organs situated at a distance from it. In many cases the diagnosis is easily made because there are so many more factors in the history and findings than mere pain. But only cases have been selected for discussion here in which interest lies in the unusual circumstance surrounding the onset of pain, or in which the diagnosis was difficult on account of the sparsity of clinical signs.

Herpes and post-herpetic pain in the area supplied by the fifth nerve is common enough, especially when it involves, as is usual, the first divi-

sional area alone. In elderly patients, this herpes ophthalmicus is likely to be followed by an intractable type of pain, but the diagnosis is usually easy since the history of vesicles with the residual skin and corneal scars is readily demonstrated. However, the scars may be few, and hidden by the hair on the scalp, and the history of the eruption be confused by a wrong diagnosis, such as erysipelas, at the time of the acute attack. The pain, however, is burning and numb, which distinguishes it from other pain, and its association with hyperesthesia, anesthesia and paresthesia in various parts of the area involved is typical. Herpes is less commonly found in a second divisional area. In Case 1 herpes represented part of a local meningo-encephalitis.

EPIDEMIC MENINGO-ENCEPHALITIS, HERPES TRIGEMINUS, RESIDUAL FACIAL PAIN

Case 1 (A416932). Mr. L. T., aged thirty-one years, complained chiefly of pain in the left temporal region. Eight weeks before, he had had a mild respiratory infection which had passed off in three days. Six weeks before, he had had marked diplopia which lasted about two days, followed by severe lancinating pains in the whole left side of the body, except the face. Jerking lightning-like pains radiated chiefly down the left upper and lower limbs, lasting four days, and accompanied by malaise and nocturnal delirium. Following these attacks, severe pain occurred in the left side of the face, occupying three divisional areas of the fifth nerve. This was at first sudden, severe and darting, like red-hot needles being thrust into the tissues. Later it was superseded by steady aching in the left temporal area, and numbness over the left side of the nose and left cheek. Blisters appeared over this area about three days after its onset. They became purulent and formed a raised, red, swollen patch in the left temporal area, which was incised, with evacuation of pus. Pain, steady, throbbing and burning, had persisted, chiefly in the left temporal area, but at times spreading to the cheek and lower lip.

Examination revealed scars of former herpes over the temporal area, and a moderate diminution of sensation to pain stimulation over the same area, cheek and nose. The corneal reflex was absent on the left. Examination of the spinal fluid revealed 14 lymphocytes for each cubic millimeter, and a negative Wassermann reaction. This patient was ambulant and appeared fairly well except for his very distressing and constant pain. The high lymphocyte count in the spinal fluid showed that he was not completely over the active stage of the trouble at the time of the examination.

It is well known that the pain in migraine attacks may be localized to one small area, but when it appears in some portion of the distribution of the fifth nerve, there may be difficulty in diagnosis. A person may suffer from typical migraine attacks from puberty to the fifth decade, and then, instead

of the attacks diminishing in frequency and severity, and finally disappearing, as is usual, the form of the disease may change and the pain appear in a relatively small area supplied by the fifth nerve, such as the so-called migrainous neuralgia or neuralgic migraine. The pain may appear in the supra-orbital region, the eyeball, the cheek, or in the jaws, or in the whole side of the face. More commonly it is felt in and around the orbit. The pain may be severe and frequent, or it may last for many days. The diagnosis is made from the previous history of ordinary migraine headache, from the familial history, and from the associated scotoma, nausea, and constitutional disturbance observed in ordinary types of the disease. The steady, continuous character of the pain without stimuli, such as touching or washing the face, is enough to distinguish it from paroxysmal trigeminal neuralgia.

Harris, in a recent paper on causes of persistent pain in the central nervous system, brings up the familiar term supra-orbital neuralgia, only to dismiss it, saying that the vast majority of patients having a disease thus designated were really suffering from migraine. In earlier articles, however, there are many references to what is called supra-orbital neuralgia. Putnam, in 1896, discussed the subject in an exhaustive article, mentioning the close association of "supra-orbital neuralgia" with ophthalmic migraine. Under this term he described a disease characterized by (1) a premonitory sense of depression the day before an attack; (2) boring, deep-seated or painfully pulsating pain localized to one spot, such as the eyeball, eyebrow or forehead, and associated in severe attacks with vomiting; (3) scotomas, lacrimation, congestion of conjunctiva, and change in the size of the pupils, and (4) a remarkably regular, intermittent course with attacks occurring daily for several weeks, usually at 8:00 or 9:00 a.m., and lasting five or six hours, and appearing more often in the winter and fall. Putnam discovered a familial tendency in most of his cases with a preceding history of periodic hemi-crania or generalized headaches. He admits the similarity between this disease, "supra-orbital neuralgia," and neuralgic migraine. He divides his cases into three types: (1) those in which no migrainoid or other special neuropathic tendency is traceable, (2) those in which other members of the family have had the same form of migrainoid neuralgia with perhaps a touch of true migraine, and (3) those in which the patient's attacks and

those of other members of the family approach very nearly a true migraine type. Putnam, therefore, showed the resemblance of "supra-orbital neuralgia" to migraine neuralgia to be so close that one wonders whether there is any essential difference between the two conditions. Considering all the cases of supra-orbital pain, and including those due to migraine, frontal sinus disease and ocular disturbances, and such general constitutional diseases as malaria and influenza, there seems to be little left to be called supra-orbital neuralgia. The term could be used only in the few cases remaining after the foregoing causes had been eliminated. The gradual emergence of migraine headaches into migraine neuralgia during the fourth and fifth decade is demonstrated in Case 2.

NEURALGIC MIGRAINE UNRELIEVED BY MULTIPLE SINUS OPERATIONS AND SECTION OF THE POSTERIOR ROOT OF THE FIFTH NERVE

Case 2 (A442549). Mr. A. D. R., aged fifty-four years, came to the Clinic October 1, 1923, complaining of pain in the right side of the face. His mother had had severe sick headaches all her life and the patient himself, from the age of twenty, had suffered from frontal and occipital headaches about once a week, usually beginning in the morning and lasting twenty-four hours. These were not associated with scotoma or vomiting, but there was definite nausea during the attack. Four years before, the headaches had become more severe and frequent, gradually becoming localized to the right supra-orbital ridge and behind the right eyeball. This pain seemed to replace his former headaches. He had had a submucous resection elsewhere to relieve the supra-orbital pain, but it was made worse. Six other operations were performed on the nasal sinuses of the right side, but he became worse after each operation, and in May, 1923, it was present both day and night. On this date he had had a resection of the posterior root of the right fifth nerve. The surgeon reported finding a thickened dura over the ganglion. Immediately after operation the patient had the sensation of his teeth being crowded, and the numbness usual after section of the posterior root of the fifth nerve. These sensations accompanied the pain in the right supra-orbital region, which remained the same, or was even more severe. In a month it had spread over the whole fifth nerve area.

At the time of his visit to the Clinic he complained of severe, continuous, prickling, bursting pain in the right side of the face. He said that he felt as if his scalp was being torn off and his skull crushed in. Every time he mentioned the sensation he had a new adjective for it. Pain in the left side of the mouth and alveolar margin was infrequent. Morphine had been taken to induce sleep. The patient considered his condition worse in every way than ever before. He was unkempt, irritable, and emotional, and looked the picture of utter misery. There was complete cessation of function in the right fifth nerve with abolition of sensation and motor power.

Case 2 also demonstrates the disastrous results

of surgical intervention. In cases in which operation has been performed, a state of chronic exhaustion, and nervous and emotional instability seem to result, and the original complaint is obliterated by the manifold and bizarre symptoms which increase with each operation. It is strangely true that patients with paroxysmal trigeminal neuralgia submit readily to radical operations for resection of the ganglion or section of the root, and regard the discomforts of the resultant anesthesia of the face, jaws and scalp as of minor consequence. They are ready to recognize freedom from pain and be thankful for it. They are not usually neurotic, and, as Patrick has observed, are seldom addicts of opium. Usually during paroxysms they are too busy to complain, and between their paroxysms, during remission, or after operation, too thankful to be free from pain, to indulge in any elaboration of symptoms or display of emotion. This is not true of the patients with migraine. After surgical intervention, as in Case 2, they become mental and physical wrecks, actual psychosis often developing. Something fundamentally different in the mental make-up of the two types of patients, rather than in their actual complaints, is suggested, since such different and contrasting results are obtained by surgical treatment. Migrainous neuralgia may co-exist with true paroxysmal trigeminal neuralgia, and the combination is a very confusing picture (Case 3).

ASSOCIATION OF MIGRAINE NEURALGIA WITH TRIGEMINAL
NEURALGIA. DISAPPEARANCE OF MIGRAINE NEURALGIA
AT THE MENOPAUSE. CURE OF TRIGEMINAL NEURAL-
GIA BY CUTTING THE POSTERIOR ROOT OF
THE FIFTH NERVE

Case 3 (A407163). Mrs. W. M. C., aged fifty-three years, came to the Clinic in October, 1922. She had had pain in the right side of the face for twenty-two years. Her twin sister had been similarly affected. The pain was dull and steady in the region of the right angle of the mouth, right side of the nose, right orbit and right side of the forehead. It came usually with menses, lasted thirty-six hours, and was associated with nausea and scotoma. The pain was relieved by sleep and quiet, and finally disappeared at the menopause two years before. The patient complained of another type of pain of twelve years' duration which was sudden, shock-like, and came in repeated paroxysms of a few seconds each. Talking, laughing, washing or touching the face brought on paroxysm. The pain radiated from the right angle of the mouth to the right orbit, and was relieved by alcohol injections and avulsion of the fifth nerve branches. The pain had continued after the menopause. The patient had had five years of relief from this sudden transitory pain by avulsion of the infra-orbital and supra-orbital nerves. The older, steady, periodic pain,

however, was not relieved by this or by alcoholic injections, but occurred regularly and periodically with the other type of pain until it ceased at the menopause, and left the trigeminal neuralgia to be relieved by operation.

Dana, in 1900, recognized the association of migraine with paroxysmal trigeminal neuralgia, and was even under the impression that a person with migraine may have attacks of paroxysmal neuralgia following a long period of migraine. He divided neuralgic cases into two groups. *Group 1* comprised the migrainous type of early life, and probably represents an evolution of true paroxysmal neuralgia on the basis of a migrainous neurosis. The majority of his patients in this group were women, many of whom suffered from the diffuse and steady pains of migraine with paroxysmal neuralgia. He discovered that they were made worse by operation, and explained this by the assumption that the disease did not lie exclusively in the trigeminal nerve. It is a question whether some of the cases were paroxysmal trigeminal neuralgia, or neuralgic migraine. However, from the description, Case 3 would represent this type, except that temporary relief was obtained by alcohol injection, and final and permanent cure of the paroxysmal neuralgia by root resection. *Group 2*—In the second type the patients developed paroxysmal neuralgia late in life without associated migraine, and the majority were males.

Many other cases from the Mayo Clinic could be quoted, showing the frequent association of migraine and trigeminal neuralgia. Patrick demonstrated that a high percentage of his patients with trigeminal neuralgia had suffered from migraine. Of 200 patients, forty had migraine. The diseases, however, seem to be two entities, readily differentiated and having a correspondingly different form of treatment.

Recently acquired pain in the fifth nerve area brings up the possibility of involvement of the nerve ganglion or the posterior root by a tumor. The much quoted case of Weisenburg of a patient who had had multiple operations for supposed trigeminal neuralgia, and who died of a tumor in the cerebellopontile angle, is an example. Even with our recent knowledge of the distinct character of paroxysmal trigeminal neuralgia, such a mistake is just as likely to be made now. Cushing has divided such tumors into four groups: (1) tumors in the cerebellopontile angle involving the root or ganglion of the fifth nerve by a process of extension, (2) tumors involving the gasserian ganglion

by pressure from above, (3) tumors arising in the pterygoid fossa and pressing on the second division of the fifth nerve, and (4) tumors arising primarily from the dural sheath around the ganglion.

Severe, steady, paroxysmal pain, lasting from thirty minutes to a few hours, may be the only symptom for many months before suspicion is aroused as to its cause. The pain is usually worse at night, is deep in the tissue, and is not relieved by ordinary mild analgesics. There is seldom any local deep tenderness but often superficial hyperesthesia. Other symptoms, such as numbness and diplopia, sooner or later appear, and the earliest and most striking finding is the loss of corneal reflex on the same side as the tumor. In Case 4 diagnosis was especially difficult, since there were many social and domestic irregularities in the life of the patient, suggesting conversion hysteria rather than pain from so formidable a disease as tumor in the gasserian ganglion.

TUMOR IN THE GASSERIAN GANGLION WITH PAIN IN THE FACE, AN EARLY AND ISOLATED SYMPTOM

Case 4 (A431889). Mrs. T. N. F., aged twenty-seven years, had developed severe paroxysmal pain over the right supra-orbital region twelve weeks before, lasting two hours night or day. Gradually this shifted to a spot just in front of the vertex in the middle line of the scalp, which became tender to the touch; the patient was unable to comb her hair. She had a sensation in the right eyelids, as if they were being drawn toward the nose. Six weeks before, three teeth had been pulled under local anesthetic. The sensation produced by the anesthetic seemed to persist, as a constant numbness over the right cheek developed, and pain was unrelieved. The maxillary and sphenoidal sinuses were opened and drained without relief; pain over the scalp increased in severity, disturbing sleep and rest. It was worse at night when lying recumbent, and least troublesome in the forenoon. It was always intermittent, lasting ten minutes at a time, but was severe during the paroxysm.

During the patient's stay at the Clinic numbness increased in intensity, and the area finally involved the whole right fifth nerve. The lips on the right side felt stiff and swollen, and the teeth on the right felt extra long, and there was an itching, tingling, burning feeling on the right side of the nose. Neurologic examination July 12, 1923, revealed nothing definite except subjective numbness over the right cheek. July 18, 1923, the corneal reflex on the right was slightly diminished, and pin prick was not as keenly felt on the right cheek. July 30, the corneal reflex was absent, and the masseter, temporal and pterygoid muscles were weak on the right side. There was definite anesthesia to pain over the right cheek; thermal and tactile sensibilities were less affected. The right eyeball was prominent, the right external rectus weak, and the right pupil large, and reaction on the same side was sluggish, with weakness of accommodation.

Operation was performed August 6, and a neurofibroma

(?), involving the right gasserian ganglion and its envelopes, was found.

The earliest symptom in this case was pain in the supra-orbital area, later more persistent in the scalp, near the vertex. The situation made the observer more suspicious of a functional complaint. Viewed, however, as an organic disease, this suggested a lesion, primarily of the first division of the fifth nerve, before its division into its three terminal branches. Localization of the tumor to the middle fossa of the skull seemed, therefore, reasonable. With pain in the cheek or upper lip and teeth it is more difficult to localize the tumor since it may be either inside or outside the skull. Nasopharyngeal malignancy, described by Woltman and New, commonly attacks the second or third division in the pterygo-maxillary fissure or pterygoid fossa, and also erodes the base of the skull, involving the fifth and possibly the sixth nerve inside the cranium. In such an instance, the lesion being both intracranial and extracranial, surgical intervention offers no possibility of relief. Therefore, pain, due to tumor, starting in the second or third divisional area, has a more gloomy prognosis than pain starting in the area supplied by the first division of the fifth nerve. The nasopharynx should be very carefully examined for an intrinsic tumor of that region, or for one bulging into the cavity from an extrinsic source when a patient is suffering from unexplained facial pain.

Pain in the jaws of elderly patients is a common and most distressing feature in a period of life that should be calm and peaceful. Usually, such patients have lost all their teeth and the pain is located by them in a small area of edentulous gum. Such neuralgia is well known; Oppenheim mentions it and also a senile or arteriosclerotic neuralgia occupying principally the trigeminal area in elderly patients. It is believed to be due to compression of the terminal filaments of the fifth nerve by hardened shrunken bone, and removal of the affected alveolus is supposed to relieve the suffering completely. Such patients are not usually referred to the neurologist. Many patients more than sixty years of age have had multiple operations on a certain relatively small area of the alveolus without relief. They describe their sensations as a burning, tingling, drawing, pulling, pressing or boring. The particular sensation is described with many gestures and with great feeling. In the quavering, high pitched voice of senility there is poured forth a flood of vituperation on the alleged

clumsy operators who in vain incised, scraped and injected the area which revealed nothing unusual on inspection, beyond previous intervention by all the methods known. The sensation is constant day and night, destroying sleep, rest, and mental equilibrium. Also, these patients sometimes complain of burning, prickling sensations in the tongue, numbness in the lips, and crawling sensations around the teeth, although usually their particular complaint is confined to one small area at a time. There is a strong suspicion that many of these patients owe their complaint to vascular insufficiency in the ganglion or brain stem. Perhaps, also, the sensation may be part of a senile, mental disturbance. Certain disturbances may originate in a mild pain or paresthesia and ultimately reach the state of a somatic delusion in an actual psychosis (Case 5).

THE SOMATIC DELUSIONS OF SENILITY

Case 5 (A250824). Mrs. J. W., aged fifty-nine years, came to the Clinic November 13, 1918, complaining of a drawing, pulling sensation in the right upper alveolus. Twelve months before, she had developed a steady ache in the right upper incisors. These were extracted, without relief, and she was given three alcohol injections into the infra-orbital nerve, also without relief. The portion of the alveolus corresponding to the pain area was then resected and immediately a pulling, drawing, tightening sensation replaced the previous pain. The patient had attacks of unconsciousness, followed by rigidity and sleep. Four months before, the infra-orbital nerve had been avulsed without changing the condition, and a second attack on the nerve produced no beneficial effect.

Examination revealed a much scarred alveolus and an area of anesthesia corresponding to the infra-orbital nerve avulsion. A diagnosis was made of psychalgia, but the true nature of the complaint was not determined. The patient returned a year later and a residual granuloma on the left upper alveolus was removed, resulting in an increase of symptoms. Her complaints became louder and more persistent day and night, of the unpleasant sensation on the right side of her upper jaw. One month later she again returned, and said that a bug the size of a bean was living in the tissues of her right upper gum. Every operation had secured a piece of it, but no one had found the head of the creature, so that it was always able to grow again. She feared that it might leave her gum, descend to her stomach and devour her entrails. Everyone had done their best, but no one had found the head of the devouring insect.

Senility was rather premature in this patient, and the real nature of her complaint remained long unrecognized, partly on this account and partly on account of her faulty knowledge of the English language. When she actually developed a delusion is not known, but we made no further parasiticide attempts.

The diagnosis of hysterical pain is always made with hesitation, and it should be made on stronger grounds than the absence of definite and visible pathologic findings. In certain cases, however, certain features of the pain, when considered in connection with the personality and the social life of the patient, suggest that a cause for the pain may be maladjustment of the higher psychic mechanisms. Emotionally unstable, at war with themselves and the world, such patients produce symptoms that are the outward manifestations of this inward struggle. As Gordon and Carleton have recently suggested, strong suggestion combined with internal and unresolved conflict in a predisposed ill-balanced person can be the exciting factor in producing almost any form of pain or ache. Usually a review of the personality of the patient, the life history and the reaction to environment, gives the clue to the actual mechanism of pain production. The pain frequently varies with factors tinged with a high degree of emotionalism in the daily life. Often, however, pain in such cases is more constant than in actual somatic diseases. The pain of organic disease is usually intermittent, but suspicion should be directed to pain present constantly day and night, never worse and never better. Often the patient confesses that the "pain" is not so much pain as a peculiar, distressing, ill-localized and deep-seated sensation (Case 6).

HYSTERICAL PAIN IN THE RIGHT CHEEK

Case 6 (A382189). Mrs. F. W., aged thirty-four years, came to the Clinic January 28, 1922, for relief from pain in the right cheek. The first attack had come on seven years before, at 4:00 a. m., lasting until 11:00 a. m. Thereafter it had appeared at intervals of a month to a week, necessitating rest in bed until noon, with breakfast in bed. She described it as a steady, severe pain commencing in front of the right ear and radiating into the right eye and into the right temporal region. Pain was absent during the day and on occasions when she was away from home, free from work and responsibility. Close questioning elicited the information that the pain always followed coitus. She had been sexually frigid during her entire married life, and only yielded from a sense of duty. When her husband was away from home the pain ceased. She herself did not realize this association, but believed that disease of her pelvic organs caused the pain, and came to the Clinic primarily for pelvic operation. She was emotionally unstable, excitable and voluble, and was disappointed because no attention was directed toward her imagined pelvic disease, and no suggestions made with regard to the removal of her reproductive organs.

Many hours of careful examination were required in this case to elicit the true story. The factors associated with the pain were submerged, and

the patient herself regarded them as of small consequence and only at the last moment mentioned her distressing marital relationship. The desired gynecologic operation of castration or hysterectomy probably represented a wish centered around relief from all sexual contact. The pain itself acted as an excuse and a solution of her conflict. The patient left the Clinic hurriedly as soon as she found operation was not advised, and, unfortunately, further observation was impossible.

Hysteria may be a reaction throughout life or it may occur in certain phases of existence, dependent on stresses and strains. There are, however, persons whose mental endowment is poor, and in whom a certain rôle seems necessary for the satisfactory working of their cosmos. The evidence of maladaptation may appear in small and trifling tics and mannerisms, or be severe enough to necessitate the assumption of a life of chronic physical and social invalidism. Such persons are either hypochondriacs or mendicants, who fill hospitals and workhouses. The enumeration of their lifelong sufferings with the various ill-advised procedures used to relieve them is to them an engrossing occupation. Sometimes they write their autobiography, and are as proud of relating the vicissitudes of their career as Job was to detail his misfortunes. Always they end with the remark that no one has cured them, and offer their latest medical counselor the opportunity to perform a miracle and change their whole life pattern. Case 7 is an example of our error in attempting to change a situation developed from heredity, and persisting throughout life.

MULTIPLE OPERATIONS ON THE RIGHT SIDE OF THE FACE, TWO
INTRACRANIAL OPERATIONS ON THE FIFTH NERVE
AND PERSISTENCE OF SYMPTOMS

Case 7 (A265657). Mr. C. J. P., aged fifty-four years, came to the Clinic April 10, 1923, complaining of pain in the right cheek of twelve years' duration. The onset occurred with the extraction of the right upper bicuspid tooth. The attacks of pain lasted from two to fourteen days every three months. Eight years before, a diagnosis had been made of sarcoma of the right antrum. Radium had been applied without relief. Five years before, the antrum had been opened and no pus found; however, within two weeks after operation there was a profuse amount of pus, and two operations were necessary to clear up the wound; the pain persisted. Four years before, he had been examined at the Clinic for the first time. He was nervous, and had pains all over his body and face. He had contracted gonorrhea which was not severe, but he had lost 15 pounds worrying about it, and most of his attention at that time was concentrated on his genitalia, and vague and peculiar symptoms. A diagnosis of "sexual neurosis" was

made at that time; the facial pain did not seem to be the dominant factor. Two and one-half years before, the pain had spread from the alveolus to the superficial tissues of the cheek, and avulsion of the right infra-orbital nerve had been performed, producing an area of corresponding anesthesia, but without relief. Several months later he had had three alcohol injections into the infra-orbital foramen, without relief, and an attempt was made to cut the posterior root. This failed since the sensory division remained intact, but the motor root was cut, with paralysis of the masseter, temporal and pterygoid muscles. Eighteen months before, the pain had spread to the right half of the soft palate, the region of the right nasolabial fold and right angle of the mouth. He had the whole anterior wall of the right antrum removed without relief. A year before coming to the Clinic, and for the first time, he developed sudden, severe, sharp pains lasting five to thirty seconds and initiated by external stimuli, such as washing his face, eating and speaking. His previous pains had been of a drawing, pulling nature. There was a definite trigger area over the right angle of the mouth. He had become depressed, sleepless and morose.

Examination revealed an extraordinary degree of mutilation over the right cheek with a depressed area over the antrum, the scar of radium burn and the patch of anesthesia produced by section of the infra-orbital nerve. There was no other anesthesia, but the right masticatory muscles were paralyzed, all being signs of operations performed elsewhere. The posterior root was sectioned to relieve more recent pains, which he declared were worse than the original pain. There was immediate cessation of the shooting, sudden pains, but he complained just as bitterly of a grinding, pressing, drawing sensation over the right cheek.

This patient's life history and his constitutional make-up were sufficient to stamp him a biologic inferior. Recent correspondence contains long rambling complaints of pain worse than before, and philosophic discussions of his misery and suffering. It is possible that this patient and others of the same type terminate in state hospitals with a psychosis of which the earliest signs were present at birth.

The pain of angina pectoris may be referred to various zones of the trunk and extremities. Willius has described unusual locations for this pain, but rarely is one tempted to assume that pain in the upper and lower jaws belongs in this category (Case 8).

ANGINA PECTORIS REFERRED TO THE RIGHT SIDE OF JAWS

Case 8 (A311057). Mr. O. R., aged seventy-three years, came to the Clinic April 9, 1920, complaining of paroxysmal pain in the right upper and lower jaws, that came on once or twice a day, usually when he walked up hill just after breakfast. Excitement, anger or hard physical exertion always precipitated the attacks, which lasted about thirty minutes. The pain was steady, severe and reached a maximal severity with rapid diminution at the end of the attack.

Alcohol injections of the infra-orbital and inferior dental nerves had been given without relief.

Examination revealed marked arteriosclerosis and myocardial degeneration. Electrocardiograms revealed arborization block, and roentgenograms, marked enlargement of the heart to the left. The pain continued until the patient died three years later. He was relieved temporarily by amyl nitrite inhalations; deep alcohol injections of the fifth nerve did not relieve him. During the last year of his life the attacks of pain radiated down the left arm. He died, apparently from cardiac failure.

The diagnosis in this case was made on the definite association of pain, exercise, emotions and the usual factors bringing on an anginal attack. Clinical investigation revealed enough cardiovascular disease to substantiate this assumption, and the relief produced by amyl nitrite inhalations further substantiates such a diagnosis. At the time the patient was examined at the Clinic the pain did not radiate down the arm, but it did later. The patient eventually died of cardiac insufficiency.

These are only a few of the cases of pain in the fifth nerve area, and they represent but a small part of the problem of diagnosis. There remain a large number of case records in our files in which no satisfactory diagnosis could be made, of which Case 9 is an example.

FACIAL PAIN OF UNCERTAIN ETIOLOGY

Case 9 (A250831). Mrs. W. T., aged thirty-eight years, had an exploratory laparotomy May 14, 1921, and a diagnosis of linitis plastica was made. Immediately after the operation she had constant slight burning pain over the second and third divisions of the left fifth nerve, as if burned by the ether. This continued unchanged until August 9, 1923, in the meanwhile extending to include the first division area, the left side of the tongue and the inside of the mouth. The condition was not influenced, except that it was worse with fatigue, and after exposure to cold wind. There was also dull aching pain around the left orbit, especially at the outer margin. This was not constant, occurring about every three weeks.

Examinations of teeth, sinuses and local structures were negative, as was the neurologic examination. Cocainization of the right sphenopalatine ganglion made the pain worse. No definite diagnosis was made.

This case represents a vague, intangible group of symptoms and, although simply detected, extraordinarily difficult to interpret. The patient has pain that seems to fit into no known category, and corresponds to no known classification. There are many such patients seeking relief, and often failing to get it. Their disease is often disguised by terms, such as facial neuralgia, which mean nothing to the physician, but usually satisfy the patient. Until the cause is known, treatment, obviously, is inefficient, and too often consists of analgesic remedies

that give only temporary relief. Surgery makes the pain worse, and until there is a more complete understanding of what these symptoms signify, there can be no progress toward cure. As a symptom, pain in the area supplied by the fifth cranial nerve requires the utmost skill and patience of the diagnostician to interpret, and only too often a reasonable conclusion as to its significance cannot be reached. Further study, observation and research may in the future clear up these problems as well as correct many of the mistaken ideas at the present time.

DISCUSSION

DR. ANGUS MORRISON, Minneapolis: Dr. Parker has very ably presented the different clinical conditions which may be responsible for pain in the area of distribution of the fifth nerve. The matter of determining the cause of such pain in certain cases is not always easy. When we have determined the cause, we are often able to alleviate the pain by alcoholic injections or by a more radical surgical procedure; in other cases, those which are due to a psychoneurotic cause, by helping the patients to adjust themselves in facing their situations.

However, as Dr. Parker has mentioned, there is a group of cases having pain in the area of the fifth nerve for which no etiological factor can be found. Dr. MacGibbon, who will follow me in the discussion, has some very interesting

facts, not only as to the possible cause of at least some of those cases falling into the group of unknown etiology, but also a method of relieving the pain in this particular group.

Before discussing this further, I would like to hear what Dr. MacGibbon has to say.

DR. E. E. MACGIBBON, Minneapolis: Although I am supposed to discuss Dr. Parker's paper, I am not qualified to talk on the subject of tumors, migraine, etc. I can only speak of pain in the area supplied by the fifth cranial nerve from the dental viewpoint.

Dr. Parker states that there are a number of cases, the etiology of which is not known. We hope to explain the etiology of a percentage of this group of cases by a theory of ganglionic trauma resultant from abnormal mandibular movement.

Let me explain our point with this chart of the lingual aspect of the right mandible, ascending ramus, Gasserian ganglion and the numerous nerve trunks and foramen in this locality. You will notice that the mandibular nerve leaves the Gasserian ganglion through the foramen ovale and passes through soft tissue to the mandibular foramen, where it again enters bony structure. Cunningham's Anatomy and other anatomists tell us that in the normal mandibular movements this nerve trunk is subject to a slight strain.

In patients who have suffered the loss of teeth, abrasions or malocclusion, we have abnormal mandibular movements which put an additional strain on the mandibular nerve trunk and also the Gasserian ganglion and its branches.

Working on this theory we have restored facial dimensions and stabilized the mandible by the means of artificial dentures and brought about relief of the neuralgia symptoms over a period of one to four months; the pain returning when the patients became accustomed to their plates and returned to excessive mandibular movements again. These plates were taken from the patients for a few days and the neuralgia returned and was relieved shortly after the plates were inserted again.

One patient I remember very distinctly. We took his lower plate from him, unbeknown to him, because we wanted to see if the pain would return. Two days later he was at the entrance to the Clinic in the early morning waiting for it to open so he could get his plate back. He was biting on a piece of wood to hold his mandible quiet to try to prevent the neuralgia.

You will notice these people talk with their mouths closed, they do not enjoy eating, and they are always trying to keep the mouth quiet for fear that the pain will return. That is why I think when patients say they have had a tooth extracted and feel better for a few days, it was due to a sore mouth which the patient was favoring. Working for three years on this theory of ganglionic trauma due to abnormal mandibular movements our results have been so gratifying we cannot help but feel that herein lies the cause of a percentage of these cases of paroxysmal trigeminal neuralgia.

I say "we" all through this discussion, because my associate, Dr. W. K. Haven, deserves every bit as much credit as I do for this work.

In closing I would like to give a technique that is painless for the relief of paroxysmal trigeminal neuralgia. A

number of authors speak of a trigger or one nerve trunk that seems to set off the tic. With this thought in mind I have found this nerve trunk in a large number of cases by a process of elimination with a series of novocaine injections. After finding this trigger, it was injected with two per cent novocaine, followed ten minutes later by the alcohol. I have been able to relieve the tic neuralgia in each case for a period of several months.

This has an advantage over the other alcoholization by injecting one trunk only instead of several, as has to be done in severe cases if several nerve trunks are involved in the neuralgia.

DR. THOS. B. HARTZELL, Minneapolis: I would like to add a word to this discussion. About five years ago, Dr. Silverman, of Atlanta, Georgia, gave his experiences with some 20 or 25 cases; and he pointed out the fact that that branch of the fifth nerve that passes around the coronoid process is frequently the one at fault. It was through him that I described the method of singling out the offending nerve by anesthetic injection into the several trunks, thus finding the offending trunk which when injected gave relief from pain. Since reading his article I have seen quite a considerable number of cases of so-called trifacial neuralgia, and I have had three in which that branch which is illustrated in the picture as passing around the coronoid process has happened to be the one. Whether or not that is due to the fact that that branch is bent and flexed a good deal in the act of mastication, I do not know; but I do know that when that one does happen to be the branch, if you will load it with alcohol, usually the neuralgia is relieved. It was, in these three cases, at any rate.

DR. ARNOLD SCHWYZER, Saint Paul: I want to emphasize the one point that if you have a neuralgia in the face you should examine minutely all of that side. Two cases made that very clear to me. One case was brought in, an Italian with a tremendous tic douloureux apparently in the orbit and in the supra-maxillary area. We found a bad tooth in the lower jaw, an infected tooth. He didn't think that that could be the cause, but he had it pulled, and he has remained well since. That is not so very recently; it is at least over a year.

The other one was a case of a nurse who had a number of things done to her tic. She had very severe attacks, and she was dozey from morphine. Again we found a tooth that brought on these tics—this time in the upper jaw. The tooth was removed and that relieved the condition. She was apparently not entirely free from pain during my summer vacation; she had some pain, and she went back to the dentist. There were three or four teeth behind the bad one, which were perfect, and this dentist drilled every one of these teeth and took the roots out so as to relieve the pain (!). Now those were good teeth, and they were criminally damaged that way.

In 1903 I went to Munich to see the man who first brought out these alcohol injections in trifacial neuralgia. Professor Schloesser was doing that work. He complained bitterly that some other people had stolen his idea and had published things. One thing that I saw and which seemed to me particularly good and valuable was this: He has an entirely different method from the usual one to inject the

third branch, and his is so simple that a man with a reasonable amount of dexterity can do it out in the country, if he just tries first on an ordinary skull. You take the lower jaw; you outline the ascending branch with your fingers; then go directly in the axis of this ascending branch in with a long needle, which is not too pointed, but rather cut off less obliquely than the usual hollow needles, and you just advance that needle upward on the inside of the jaw, always exactly in the line of the ramus ascendens. When you are halfway up you find you hit a little bit of a prominence. There is a little prominence just over the entrance of the dental nerve, the lingula, and that as a rule you can make out very easily. Then if you push the least little bit ahead, the patient will tell you he has pain in his teeth; and if you should inject a little bit of alcohol, he will tell it to you in a vivid way. Then you can go up further and you strike the part where the third branch gives off the lingual nerve; and if you strike that he will tell you he has pain now also in his tongue. Then you go straight up to the base of the skull; you cannot hit anything dangerous there; and all you have to do is to feel with the point of your needle along the skull, moving the point of the needle gradually inward until you come to a depression. This depression is the foramen ovale.

I have demonstrated this to many doctors and had them try it, and they usually hit it the very first time. The fact is that if you don't always hit it, you can inject a little and feel your way through until the patient is very emphatic, and then you are sure you have hit the nerve.

Twenty years ago (I had just come home from Europe) I had an extreme case of tic douloureux, a most pitiful

picture. I injected alcohol there several times; and I just saw that woman's granddaughter last week, and she told me that the patient has remained absolutely well. So even in fierce cases of tic douloureux, which are known as a rule not to yield to alcoholic injections, you are liable now and then to get a good result, a permanent result.

DR. H. L. PARKER, Rochester (closing): I am very grateful for the liberal discussion that my paper was accorded, and I regret that my time was not long enough to permit me to bring up the question of therapy. Therapy in these cases is, of course, a very difficult matter and the cases that I had selected for discussion were in the majority very severe ones wherein almost every form of therapy had been attempted in vain. In most of them there had been too much therapy.

I hardly like to enter into the discussion as to the etiology of trigeminal neuralgia since, of course, that has been more or less carefully gone into in the last decade. The assumption as to the cause of the disease from the success of a given treatment is a very risky one unless the patient has been followed over a long period of time, since such cases tend to go into spontaneous remissions whereby it may be erroneously inferred that they have been cured.

I was particularly interested in Dr. MacGibbon's discussion as to the cause of a particular type of pain in the face and I assume that he was particularly referring to the type designated paroxysmal trigeminal neuralgia. He has offered a very definite and common sense therapy and I feel that in the future when this has been thoroughly tried out new interest and new light will be cast on the whole subject.

PAYMENT OF ANNUAL DUES

The fiscal year of most of the state medical associations has been made to correspond with the calendar year. It would undoubtedly simplify matters considerably, so far as records of county, state and national societies are concerned, if the calendar year coincided with the fiscal year in all states, but some of the oldest associations prefer to adhere to long established precedent and their wishes in the matter are supreme and are accorded the fullest respect.

In all state associations which begin their fiscal year on January 1, state dues are payable on that date and, of course, dues to county societies are payable at the same time. There are very few members, if indeed there be any at all, who are not fully aware of that fact, but there are a great many who, through sheer carelessness or otherwise, neglect to send their dues to county secretaries for weeks or even months after they have become payable. Some societies are very lenient in the matter; some, indeed, are entirely too lenient. Others are very strict and drop from their membership rolls all who have not paid annual dues by January 1. In most instances, state associations whose fiscal year begins with the calendar year allow the names of delinquent members to remain on the roster until April 1, at which time they are dropped if dues are still unpaid.

The membership roster of the state association is made up of the names of members reported by the county secretary to the state secretary; the membership roster of the American Medical Association is made up of the names of members reported by the state secretary to the secretary

of the American Medical Association. Obviously, a man who does not pay his dues to his county secretary at the right time need not expect his name to appear on the list of members of the state association or on that of the American Medical Association. The county secretary who does his full duty has enough to do without having to be everlasting after members to pay dues when due. Incidentally, the state secretaries and even the office of the Secretary of the American Medical Association are reasonably busy. It costs medical societies money when the secretaries have to enter, drop and re-enter names, over and over, year after year. But aside from all that, membership dues should be paid and paid promptly when due just because it is right that they should be so paid.

As is pointed out in another column in this issue of the *Bulletin*, the reapportionment of delegates from the state associations to the American Medical Association will be made at the next annual meeting in Chicago. This will be effective on the basis of the membership of state associations as they have been reported to the American Medical Association, April 1, 1924.

While reminding members of their duty to pay annual dues at the right time, it may not be amiss to remind those county secretaries who are negligent about reporting to state secretaries—and there are such—that such negligence works hardships and injustice on members who have paid their dues and who are entitled to have their names properly recorded on the membership rolls of state associations and the American Medical Association.—*A. M. A. Bulletin*.

TUMORS OF THE SPINAL CORD: SURGICAL TREATMENT AND RESULTS*

ALFRED W. ADSON, M. D.

Section on General and Neurologic Surgery
Mayo Clinic, Rochester, Minnesota

Inasmuch as surgical treatment of tumors of the spinal cord offers the only possible relief for patients so affected, and since 50 per cent of such tumors exposed at the time of operation are removable, it is imperative that careful examination be made of patients complaining of root pains or atypical abdominal pains, and also of anesthetics and paralyzes of the extremities, in order to rule out the possibility of tumors of the spinal cord. It is also very important to make a diagnosis early, before paralysis becomes too marked, since the recovery following surgical treatment of patients whose complaints are of short duration is more complete and rapid.

PATHOLOGY

The type of tumors of the spinal cord depends on the origin of the neoplasm; those arising from the vertebrae and from the tissues of the spinal canal are bony, cartilaginous or fascial; those arising from the meninges are endotheliomas, fibromas, psammomas, and so forth. Such tumors, as a rule, are not very large, are slow growing, and rarely malignant; their early removal favors ultimate cure. Tumors of the cord itself are usually gliomatous, and arise around the central canal; some degenerate and become cystic, others remain firm and solid. Ependymal gliomas arise from the conus and extend downward through the canal of the lumbar region, and occasionally to the sacral region. Most ependymal gliomas in the lumbosacral region are encapsulated and not adherent to the lumbosacral roots, but may be situated between them and fill the spinal canal. Besides the ependymal cell gliomas in the area of the cauda equina, large cystic, degenerating neurofibromas sometimes occur, which develop slowly and erode the laminae; they also produce blocking of the spinal canal and there is likely to be yellow spinal fluid below the tumor.

SYMPTOMS

A thorough history is invaluable in making a differential diagnosis in these cases, since the complaint at the onset may be only a slight sensory or

motor loss followed by an increase in the severity of the initial complaint, with a greater sensory loss or paralysis until there is complete loss of all sensation and motor power, besides increased reflexes below the level of the segment involved. Bladder, sphincter, and sexual control disappear last in cases of extramedullary tumors, but disappear early in cases of intramedullary tumors. The combination of symptoms depends on the relation of the tumor to the spinal cord: those arising dorsally will first produce sensory changes; those arising anteriorly, motor disturbances, and those arising laterally, the Brown-Séquard's syndrome. Tumors arising from or attached to spinal nerves will produce pain, while those originating in the meninges or cord without coming in contact with a nerve root may develop without pain. In many instances the initial symptom is pain, but as anesthesia progresses the pain frequently diminishes, and may be absent at the time of examination.

It has been customary to defer laminectomies until the patient presents a definite sensory and motor level, and it is not uncommon to examine patients who have undergone various laparotomies for pain, without relief, when in reality they were suffering from root pain. A number of patients have been explored recently in the Mayo Clinic who complained of excruciating root pain without impairment of motor function, and with or without slight sensory disturbances. The pain of which such patients complain is very similar; it usually radiates along the distribution of one or both sciatic nerves, and is associated with or without tenderness over the upper lumbar spine. The pain is exaggerated by coughing, sneezing or bending forward, and also when the patient lies down, becoming so severe that he is compelled to leave his bed and walk around; it is unlike the pain of true sciatica, which is relieved when the patient reclines and flexes back and extremities. Tumors of the cauda equina are likely to produce pain for months before sensory or motor disturbances appear. A good rule to follow is thorough examination of the patient who complains of sciatic pain, but is not relieved by the usual treatments for sciatic neuritis and sacro-iliac disease. Besides the neurologic examination, differential pressure determinations of the spinal fluid of the cisterna magna, and of the spinal fluid at the fourth lumbar interspace, may be of some diagnostic value. If there is a block in the spinal canal, the pressure of the fluid in the cisterna magna is

*Read before the Minnesota State Medical Association, St. Paul, October 10 to 12, 1923.

greater than in the fluid at the fourth lumbar interspace when the jugular pulse is compressed. This blocking can be produced by inflammatory lesions of the meninges, but it is more likely to be caused by a tumor of the spinal cord. Pneumography of the spinal canal may prove of some assistance in determining the character of the lesion, but usually, if careful neurologic examinations are made, the levels of anesthesia and paresis can be elicited early in the course of the disease. Spinal punctures also are of diagnostic value. When yellow spinal fluid is obtained by puncture, it too suggests blocking of the spinal canal. The Nonne test is often positive in cases of tumors of the spinal cord, but the average cell count is normal and the Wassermann test of the spinal fluid is not made positive by the presence of the tumor.

SURGICAL PROCEDURES

No special technic is required in laminectomies for the removal of tumors of the spinal cord, except the precaution against traumatizing the cord, or permitting hemorrhage within the dura. The spines and laminae are removed; the muscles are closed in two planes with interrupted and continuous sutures of catgut, and the skin is closed by a subcuticular stitch of catgut, and a dermal suture. If the tumor is in the cervical region, unilateral laminectomy is performed, with removal of the lamina opposite and the spine over the tumor. This precaution is taken because one patient had a recurrence of symptoms owing to slipping of the bodies of the cervical vertebrae, which caused traction and pressure on the cervical cord, and resulted in paralysis. I prefer the one-stage laminectomy, but have found it necessary to perform the two-stage in seven cases, and a three-stage in one, because the lesions were so extensive. As a rule, three spines and laminae are removed before the dura is opened; five or six can be removed with little difficulty. Ependymal cell gliomas of the cauda equina usually extend from the eleventh dorsal to the first or second sacral vertebra, and in such cases there will be complications if too much is attempted at one operation. Otherwise, the one-stage operation is very satisfactory, especially to the patient.

THE ANESTHETICS

Ether has been employed as the anesthetic in most cases; however, obese patients and patients who are poor surgical risks have been operated on very satisfactorily under paravertebral anesthesia. It is necessary to apply a one per cent solution of

novocain to the dura, which is exposed during laminectomy, and is not desensitized under paravertebral anesthesia. A few drops of the solution can be injected into the dural canal above the tumor without danger. Novocain can also be used to produce intraspinal anesthesia in low laminectomies of the lumbar and sacral regions, but should be used cautiously, if at all, in middle dorsal or upper dorsal lesions.

POSTOPERATIVE CARE

The care of patients after laminectomy differs little from their care after other operations. Preferably for three or four days, the patient is kept on his abdomen on three or four soft pillows, his head slightly lower than the operative field, always avoiding undue pressure on the bony prominences. He is then permitted to turn on his side, and after ten or twelve days to lie on his back. About the fourteenth day he may sit up in a chair. He is more comfortable in the prone position, the wound heals more rapidly, and there is less danger of drainage of cerebrospinal fluid, especially in cases of intramedullary tumors in which the dura is left open. Provided the patient has not previously been catheterized, the bladder is allowed to overflow. If there is cystitis and the patient has been catheterized, a retention catheter is inserted before operation, and changed about once a week. The bladder is lavaged daily with a two per cent solution of boric acid, and about 15 c.c. of a 10 per cent solution of argyrol is introduced and allowed to remain in the bladder for one-half hour. If there is any evidence of pyelitis, acid sodium phosphate and hexamethylenamin, seven grains of each, three times a day, are administered. This is followed by a week of rest, then a second course of medication.

SURGICAL TREATMENT AND CONVALESCENCE

Extradural and intradural but extramedullary tumors can usually be removed completely with very little difficulty, but intramedullary tumors are difficult to remove. In my experience one endothelioma only could be removed completely; this tumor arose apparently from the pia mater and extended into the cord. In several instances I have attempted partially to remove intramedullary tumors, and sometimes have split the cord dorsally and permitted the tumor to extrude. The results have been twofold: certain patients have been made worse, others have improved for a time and then symptoms have recurred. As a whole, the results of removal of intramedullary tumors are unsatis-

factory, and I believe that, unless the tumor is very close to the dorsal surface of the cord, less damage will be done and more temporary relief afforded the patient by laminectomy and dorsal incision of the cord. The administration of radium may prove of some value; one patient apparently improved; another improved for one month following partial removal of an intramedullary tumor and then failed until he was paralyzed completely. If radium is used, it should be screened very carefully, and not placed directly on the cord.

Recovery depends on the duration of symptoms. If the tumor has been removed without trauma, a patient who has had symptoms for one year or less may be expected to recover completely, and if he has had symptoms for not more than three years, to improve markedly. Recovery is more complete following the removal of soft tumors than hard, nodular ones; and, if the same degree of paralysis exists, recovery is more complete if the tumors are in the caudal or lumbar region, than if in the dorsal or cervical region.

MAYO CLINIC CASES

The records of the Mayo Clinic from January, 1910, to October 1, 1923, show that 151 patients with a diagnosis of possible tumor of the spinal cord have been explored. Eighty-eight of these patients were males, and sixty-three, females. The oldest patient operated on was sixty-five years, and the youngest, twelve years; the average age was forty-one years. For purposes of study the patients were divided into nine groups:

Group 1.—Twenty-one patients with extradural tumors.

Group 2.—Forty-six patients with intradural but extramedullary tumors.

Group 3.—Forty-one patients with intramedullary tumors.

Group 4.—Thirty-two patients in whom no tumor was found. Some of these patients had chronic meningomyelitis, and in four, tumors were found later.

Group 5.—Four patients with angioma (varicose veins) of the spinal cord. One patient gave a positive history of syphilis.

Group 6.—Only one patient in whom an echinococcus cyst of the cord was found; she had been operated on for echinococcus cysts of the lung and liver.

Group 7.—Two patients with tuberculoma of the cord, one of whom had an extensive tuberculoma on the anterior and lateral surfaces of the cervicodorsal cord, associated with miliary tuberculosis; these findings were verified at necropsy. The other patient had unilateral inflammatory lesions of the cauda equina, resembling tuberculoma without neoplastic cells; the condition had not progressed since 1917.

Group 8.—Two patients with gumma of the cord; both gave histories positive for syphilis, and presenting definite levels of paralysis. In one the meninges were thickened and adherent to the cord in a large mass for 4 cm. The other patient gave a history of symptoms for about six months, and presented much the same findings except that the dura could be separated from the soft inflammatory mass. Part of the mass was removed at operation, the wound was closed, and the dura left open. The patient recovered his motor power and sensation, and was apparently free from symptoms for four years following operation, after which there was no further record.

Group 9.—Two patients with cerebellospinal tumors; the age of one patient was forty-eight years, and of the other, two and one-half years. Both had tumors of the vermis, extending through the foramen magnum into the spinal canal. Partial removal only was possible, and both patients died soon afterward.

Duration of symptoms.—The average duration of symptoms was twenty-nine months in Group 1, fifty-two months in Group 2, forty-one months in Group 3, and forty-five months in Group 4. The number of patients in the other groups is too small to permit of a fair estimate.

Root pain.—Fourteen patients, two-thirds of the number, in Group 1, had root pain, it was present in thirty-six patients (78 per cent) in Group 2, in thirty patients (73 per cent) in Group 3, and sixteen (50 per cent) in Group 4. Two of the four patients in Group 5 had root pain, and four of the seven patients comprising Groups 6, 7, 8 and 9 (57 per cent) had the pain.

Paralysis, and motor and sensory disturbances.—While sensory paralysis and motor disturbances are the predominating symptoms, it is not uncommon to see patients with only one or the other. Nine of the 151 patients had no motor disturbance, ninety-eight had partial motor disturbance, and

forty-four had complete paralysis below the level of the lesion. Ten patients had no sensory disturbance, eighty-six had partial loss of pain, tactile and temperature sensibilities; fifty-five had complete loss of sensation below the level of the lesion, thirty-four had no bladder disturbance, seventy-six had partial loss of bladder control, forty-one had complete loss of bladder control, twenty-nine had no loss of rectal sphincter control, seventy-three had partial loss, and forty-nine total loss.

SPINAL FLUID FINDINGS

These findings reveal the frequency of xanthochromia, high cell count, globulin and positive Wassermann reaction. One hundred seventeen spinal punctures were made on the 151 patients operated on. Xanthochromia was found in the spinal fluid in fifteen; there was a positive Nonne test for globulin in fifty-six, and the average cell count was three in those in whom the count was taken, the highest count being 29. In all the Wassermann reaction on the spinal fluid was negative, although three patients gave histories positive for syphilis.

LOCATION OF TUMOR

In seventy-eight patients, the tumor was in the dorsal region; occasionally it extended into the cervical and lumbar areas, but the principal portion was in the dorsal region. In twenty-six patients, the tumor was in the cervical region, in fifteen in the lumbar, and in four in the sacral. In twenty-eight no tumor was found, or the symptoms were caused by an inflammatory process.

Sixty-one tumors were completely removed (50 per cent of the 119 tumors found), and thirty were partially removed (25 per cent). In thirty-two patients, no tumor was found at the time of operation, the lesion being a meningomyelitis, or a tumor which was missed. Four patients of the series proved later to have had tumors, two endotheliomas of the cord, and two, Middeldorpf tumors of the sacrum. In twenty-eight instances it was impossible to remove the tumor.

END-RESULTS AND SUMMARY

The records of patients operated on from 1910 to the present time are reviewed; patients operated on during the last year or two have not, of course, had sufficient time to experience the maximal amount of improvement, and therefore the end-results should be better than they now seem. One hundred eight of the series of 151 patients are living; thirty-three are perfectly well and working;

six are improved and doing some work; thirty-five patients are improved, but not working, and six improved for a time, but their symptoms returned due to progression of the lesion. Fifteen of the patients are helpless, and thirteen were not traced. One hundred sixty laminectomies were performed on the 151 patients, seven patients having had two laminectomies and one a triple laminectomy for extensive lesions.

One hundred nineteen neoplasms were found at the operating table, 80 per cent of which had been correctly diagnosed. Sixty-one tumors were removed completely, 50 per cent of the total number found, and thirty tumors were removed partially, 25 per cent of the tumors found. Thirty-three of the patients were cured and working, 36 + per cent of the number in whom tumors were removed or partially removed, six patients were improved and doing some work (6.5 + per cent), and thirty-five were improved but not working (38 + per cent). Seventy-four patients improved following operation, which was equivalent to 48 per cent of the 151 in whom laminectomy was performed, or to 62 per cent of the 119 patients in whom tumors were found.

DISCUSSION

DR. J. FRANK CORBETT, Minneapolis: Dr. Adson's descriptions were so graphic and the whole paper so pregnant with suggestion that I hesitate somewhat in trying to add anything to that paper. However, in a very homely way I shall try to bring before you the picture that we so often see: An individual with complete motor paralysis, complete sensory paralysis, paralysis of the bladder and rectum, covered with bed sores, tortured with pyelitis, awaiting death. That is the picture of spinal tumor that we sometimes see; and it for the reason that we do see these advanced cases that the results of spinal surgery are not better than they seem to be. All of these cases—or the great majority—at some time were operatable; but the diagnosis of spinal tumor is difficult. So many times the picture is so indefinite that these cases have been treated for pleurisy, have been treated for gall-bladder disease, have perhaps had every conceivable operation done upon them except the one they needed. Then finally after a long series they come to the neurologist and to the surgeon for operation. Dr. Adson's talk has done much to clarify the diagnosis. He could not by any means go into all of the details; but he has hinted at many things that I think will be of value to all of us.

In regard to the treatment I am thoroughly in accord with what Dr. Adson has said in regard to the two stage operation. It frequently is necessary to remove a large number of laminae. There is bound to be some hemorrhage with this and some shock. The local anesthesia lessens the hemorrhage, lessens the shock, lessens the danger that

comes from the recovery from the anesthetic. That is material. It is efficient and easily done. There are one or two places in the past where I have failed, and usually it has been on account of the one stage operation. I have tried to do too much. Particularly where you have an extradural tumor or any type of tumor that extensively involves the roots, be careful with your dissection. Always in that kind of case I should say do a two stage operation. Blocking the roots if feasible with novocaine may in some measure prevent the shock; but the most severe shock and the things that I have regretted most in my life have been too much interference with the roots. You can do a lot of surgery in other places, but you cannot do it there.

I think this is a wonderful series. I had one case, a varicosity of the spinal cord; and I thought it was so rare a case that I would dilate upon it. But much to my chagrin here Dr. Adson presents four of these cases. A simple decompression will accomplish improvement, but it is short lived, or apt to be. On the other hand, radical removal is apt to do a great deal of damage; and if attempted at all they must be removed radically.

DR. R. E. FARR, Minneapolis: In discussing this paper I feel something like a greyhound barking at an express train going by. My experience in this class of work has been very small; and still there are one or two points that I might dilate upon. Dr. Adson mentioned that there were three methods aside from those that he had given us for locating and diagnosing these tumors. He spent very little time on diagnosis, and he only mentioned one of these—perhaps forgot the other two. There is one thing that I believe it is well to call attention to at least, and that is the method of Ayer. Dr. Adson referred to this in a way when he called attention to the difference in the color of the fluid above and below the tumor. This method is, as you all know, the putting in of two needles, one above the supposed seat of the tumor and the other below, giving a difference in manometer reading, giving a difference in pulsation, from the blood pressure and from cough straining and sneezing and so on, and giving a different type of fluid from above the tumor and below. It seems to me that that is one of the best methods of diagnosis that has been brought out in recent years.

The difficulty of local anesthesia is not manifest until the cord and membrane are exposed. In the few cases that we have operated upon we found not the slightest difficulty in exposing the cord under straight infiltration anesthesia. We find it lessens hemorrhage, lessens shock. We have the co-operation of our patient and the patient can be made quite comfortable on the table. I believe the operation can be done fully as rapidly or more rapidly than if general

anesthesia is used. When the membranes are exposed, we find them exceedingly sensitive. The first one I did was especially sensitive. The use of local anesthesia may bring out what Dr. Corbett has called attention to, that is, the opportunity to avoid doing too much.

We tried two methods in an effort to produce anesthesia in spinal nerves. We tried bathing the nerve filaments in strong cocaine and injecting them with a very fine needle with novocaine. Now butin has been developed. It is almost as efficient a drug locally as cocaine, and much less toxic. I have not yet had a chance to use it, but I would suggest bathing the tissues with it in such a manner as not to allow it to get into the spinal fluid circulation in these cases. If we can get anesthesia of the local tissues after we have uncovered the cord and membranes, then local anesthesia in this work is going to mark an even greater advance.

DR. A. W. ADSON, Rochester (closing): I am very grateful to Doctors Farr and Corbett for their discussion and appreciate Doctor Farr calling attention to the differentiation pressure method of Ayers. In my discussion I intended to present Doctor Ayers' technique and Doctor Dandy's pneumography method for determining spinal block. The differentiation pressure method is very valuable in determining spinal block. Two spinal puncture needles are used; one is placed in the cisterna magna and the other into the fourth lumbar space. In the absence of spinal block the pressures are equal, but in the presence of spinal block, due to a tumor or inflammation, the pressure indicated by the manometer is greater in the cisterna magna than in the fourth lumbar interspace when the jugular pulse is compressed. This method does indicate block, but occasionally small tumors exist which do not produce block and inflammatory lesions will produce block similar to tumors; though spinal block has been determined, it is not definitely localized and needs careful neurologic examination to determine the level. Pneumography of the spinal canal has also proven of value; this procedure consists of withdrawal of spinal fluid from the fourth lumbar interspace and the injection of an equal quantity of air which seeks the upper level and indicates the block in the spinal canal which is manifested by a darker shadow on the roentgenogram.

While I have laid great emphasis upon the importance of early diagnosis and surgery in spinal cord tumors, I do not want to give the impression that every paraplegic patient has a cord tumor, but urge that the paraplegic should be given a thorough neurologic examination, and when a patient comes with atypical pains, one should not forget the possibility of existing root pains caused by spinal cord tumors.

FACTORS IN HEALTH AND DISEASE THAT AFFECT THE METABOLIC RATE*

MAX H. HOFFMAN, M.D.

St. Paul

The general term metabolism includes anabolism or the taking in of food, with its conversion into tissue and storage in the body, and catabolism or the breaking down of material in the body with the liberation of energy.

This process is an oxidative one involving the utilization of oxygen and the production of carbon dioxide. By the term metabolic rate we mean the speed at which this transformation of energy is taking place.

The determination of the metabolic rate is not an exceedingly difficult procedure, but consists in having the patient breathe indoor air and exhale into a tank. This is done for a definite length of time. The exhaled air is then analyzed for oxygen and carbon dioxide. This analysis tells us what kind of substances have been burned during the test. Knowing this and knowing how much oxygen has been used, we can calculate the number of calories that have been burned.

The difference between the metabolic rate and the basal metabolic rate must be clearly understood. In the performance of the basal test the patient must be in the state of complete rest, and must have abstained from food for twelve to eighteen hours. The calories produced under these conditions are then compared with standards obtained from normal individuals under the same conditions, and the results expressed in percentages above or below normal.

The normal energy expenditure in an adult varies between 35 and 40 calories per square meter of body surface per hour. In the newborn the energy expenditure is low. This increases for three to six years, when it begins to decline rather rapidly. At about twenty years the decrease becomes much slower. In the female the energy expenditure is less than in the male.

In this paper we propose to discuss the various factors that will change the basal metabolic rate to a non-basal rate. These factors can be conveniently grouped under the headings of: (1)

muscular activity, (2) temperature changes, (3) specific dynamic of food, (4) medication, (5) starvation.

Muscular exertion increases the metabolic rate more than any other factor; and under this head should be considered the involuntary muscular movements such as shivering, dyspnea, and restlessness. Merely sitting up in bed can increase the metabolic rate 8 to 20 per cent; sedentary work 100 per cent; moderately hard work 200 per cent, and hard work almost 300 per cent. The muscular activity accompanying a chill may cause an increase of 75 to 200 per cent above the basal rate.

It is important to think of the effect of muscular activity on the metabolic rate when the treatment of overnutrition or undernutrition is being considered.

To demonstrate this effect let us select for example a type of individual frequently encountered in practice—a high strung female, 25 to 30 pounds underweight. She is constantly on the move, thereby keeping her metabolism rate up to a high level. Her predicted basal metabolism would be 65 calories per hour. Under conditions of activity such as sweeping the floor or washing dishes she would approximately burn up 150 calories per hour. A rest of one hour after each meal and two hours additional sleep at night would save for her almost 400 calories a day, or 4,000 calories in 10 days. This is equivalent to the calories produced by burning one pound of fat in the body.

In metabolic studies in active tuberculosis McCann found the metabolism to be between 20 and 40 per cent above normal. This he believed was not the basal rate, but that the increase was due to muscular exertion accompanying cough and restlessness.

The muscular activities must be considered in the ambulatory treatment of diabetes mellitus. Formerly we had to limit the individual's activities to the level of his metabolic disturbances. At present by means of Insulin we can increase his caloric intake to allow him sufficient energy to perform his daily duties. To secure the most economical use of Insulin and to get the best result from a diet, we must know approximately how many calories are being burned up in a day. With a knowledge of the character of work being done the caloric output can be calculated within 20 per cent.

Changes in body temperature alter the metabolic rate though not to such a great degree as does

*Read in symposium at the annual meeting of the Minnesota State Medical Association, St. Paul, October, 1923.

muscular activity. The metabolic processes are a series of chemical changes, and follow closely Van Hoff's law, which states that, "For each rise in temperature of 10 degrees C. the speed of a chemical reaction increases 2 to 3 times."

A temperature of 100 degrees F. may increase the metabolic rate 40 per cent. Although there is a definite relationship between changes in the metabolic rate and changes in body temperature, they do not always run parallel. The discrepancy when present is due to other factors than to temperature, such as toxic protein destruction and restlessness.

In some febrile diseases the metabolic rate is very high. In typhoid fever as many as 5,000 calories a day are produced. This shows how extremely fallacious was the old idea of starving a fever. The number of calories fed should be governed by the height of the temperature. At least 10 per cent of the basal expenditure should be added for each degree rise in temperature.

Changes in temperature in the medium surrounding the body also alters the metabolic rate. Cold stimulates heat productions in the body; a cold douche or shower bath at 60 degrees F. may increase the metabolic rate 200 per cent. This may last from one to one and a half hours. Temperatures higher than that of the body also accelerate the metabolic rate though not to as high a degree as does the lower temperatures.

A phenomenon little known to the practitioner is the specific dynamic action of food. This is a stimulation of the metabolic rate by the ingestion of food, resulting in a loss of energy to the body. This loss must be compensated for by an additional caloric intake. Protein possesses this property to the greatest degree, stimulating the metabolism 30 to 40 per cent above the basal rate. Fats cause increase of 12 per cent and carbohydrates 6 per cent.

In typhoid fever there is a marked increase in destruction of the body protein. This acts on metabolism in the same manner as does ingested pro-

tein. This is one of the reasons why the metabolic rate in typhoid fever is higher than in many other febrile diseases.

The stimulating effect of protein on the metabolic rate should be considered in those diseases where rest is essential. An increase in metabolism indicates that the body is doing more work. For that reason McCann advises against a high protein diet in active tuberculosis.

An example of the stimulating effect of protein was related to me recently. This patient, a decompensated cardiac case, noticed a marked improvement in his symptoms following a beefsteak meal.

Practically the only drugs that have an effect on the metabolism are thyroid extract preparations and adrenalin. Thyroid extract is extensively used in stimulating metabolism in hypothyroidism. Unless very carefully used it is not without danger. The symptoms of increased metabolism, such as tachycardia, nervousness and polyuria, indicate that a sufficient amount of the drug has been given.

The potencies of the various preparations on the market differ greatly as to their ability to stimulate metabolism. Thyroxin given intramuscularly increases it 2.8 per cent for each milligram injected. The effect reaches its height in about a week and lasts about ten days.

All of the factors hereto considered act to increase the metabolic rate; starvation, however, causes a decrease. In an experiment on a fasting man there was a drop of 29 per cent in the metabolism during the thirty days' fast. This apparently is nature's method of preventing the loss of body proteins.

This review has necessarily been very brief; the time allowing hardly more than an enumeration of the various factors that alter the metabolic rate.

It is important to remember that the basal metabolic rate is the lowest energy output consistent with life, and that this rate is readily changed by muscular activity, changes in temperature, food intake and thyroid preparations.

THE VALUE OF THE BASAL METABOLIC RATE IN GENERAL MEDICAL PRACTICE*

A. E. MARK, M.D.

St. Paul

In the consideration of this subject, I shall limit myself for the most part to that field wherein metabolic studies have been of most value; namely, thyroid disturbances, laying particular stress upon exophthalmic goiter, its symptomatology and differential diagnosis.

The metabolism test has emerged from the field of medical endeavor as one of the most valuable laboratory procedures. The past decade has been very fruitful in the development of laboratory tests which have made for medical progress as nothing else could have.

Their advent, however, has been attended on the one hand too often by skepticism, and on the other hand by a too ready acceptance of the finality of their results.

Much of this has been fostered by the tendency of rendering either a positive or a negative report without a closer investigation and discussion of the case. How often are patients branded as luetic on the exhibition of a false positive reaction? False positive Wassermanns are notoriously common, as well as the occurrence of positive Wassermanns in patients with other conditions than lues.

The presence of a negative Wassermann as excluding lues; the presence of a deformed duodenal cap as always indicating duodenal ulcer; the presence of a persistently increased blood sugar with a negative urine as always being of serious consequence, are only a few of the many false interpretations which might be, and often are, placed on laboratory methods.

The metabolism test, while being by far the most reliable and accurate of the many laboratory procedures, requires the observation of many important details which, if neglected, cause it to lose its deserved prominence in medicine.

Of prime importance is the efficiency of the technician,—the attainment of this efficiency being a matter of at least six months and preferably longer. The carrying out of the test under normal conditions, especially from the standpoint of the patient

as will be brought out by others in this symposium, is of the greatest importance. The repetition and even repeated repetition of the test in doubtful cases cannot be too strongly emphasized. This applies particularly to those patients whose first estimation is from plus 11 to plus 20 or 25. I have repeatedly seen patients who have previously been considered hyperthyroid on the basis of one reading, upon whom a subsequent reading would, I am sure, have been normal. As a matter of fact, a rate of plus 11 to plus 20 or 25, in my experience, on a re-checking proves in most cases to be within normal limit. There are isolated cases of hyperthyroidism presenting a low reading, but in these the symptomatology is in harmony with the rate and as a matter of fact they are quite often unrecognized clinically.

Plummer¹ states that the basal metabolism in a given case of exophthalmic goiter must be at least plus 15 before it can be recognized clinically.

According to Boothby² at least 95 per cent of all abnormally increased rates are due to hyperthyroidism (exophthalmic goiter and adenoma with hyperthyroidism) if there is no fever.

Increased rates are constantly present in exophthalmic goiter and hyperfunctioning adenomas, in the active stage of acromegaly and in fevers. They may occasionally be found in other diseases as essential hypertension, pernicious anemia, leukemia, diabetes, bronchial asthma, decompensated hearts, tuberculosis, carcinomas, etc.

Decreased rates are present in myxedema, hypopituitarism, in cases of inanition from prolonged fasting or from restricted food intake such as occurs in anorexia nervosa, in esophageal stricture or in cardiospasm.

In diabetes and pituitary tumors, basal metabolic readings are of definite value. The advantage of maintaining a diabetic on a diet somewhat below the basal metabolic requirement has been emphasized early by Allen and DuBois³ and more recently by Wilder, Boothby and Beeler.⁴ In pituitary tumors, metabolic estimations offer a valuable aid in diagnosis as well as prognosis. Patients with low readings are poor surgical risks.

The estimation of the basal metabolic rate has been of inestimable value in many fields of scientific investigation. With especial reference to the thyroid, one might mention the standardization of thyroxin, "the active principle of the thyroid gland" isolated by Kendall,⁵ the classification and pathol-

*Read in symposium at the annual meeting of the Minnesota State Medical Association, St. Paul, October, 1923.

ogy of goiter as brought out by Wilson,⁶ the total tissue content, as well as the daily exhaustion of thyroxin, etc., as noted by Plummer,⁷ the comparison of x-ray and surgical treatment as observed by Means and Aub⁸ and others; the aid it offers in choosing the proper course of treatment, etc. In fact, its uses have been so numerous that one can only begin to enumerate them.

It finds its greatest application, however, in the differential diagnosis of thyroid diseases, especially when associated with hyperthyroidism, from neurasthenia, hysteria, effort syndrome, etc. The epinephrin test has been found to be totally inadequate to differentiate between these conditions because of its frequent occurrence in normal individuals.

There is still a misconception amongst the medical profession as to where hyperthyroidism really begins. It is especially in the differentiation of the normal from the abnormal that the metabolism test finds its great value. Unless readings from 0 to minus 10 or plus 10 are interpreted as signifying an absence of hyperthyroidism, I see no reason for using the test at all. I have repeatedly observed a tendency on the part of many men to cling to the idea that a patient may still be suffering from hyperthyroidism, or at least partial thyroid intoxication, as they express it, in spite of normal metabolic readings. I feel that this conception is fostered by the idea of periodic thyroid intoxication measured in periods of a few hours or days instead of weeks or months as is the case in patients with true hyperthyroidism.

An increased amount of thyroxin in the body requires time for its exhaustion even though the stimulus giving rise to that increase be removed.

Following thyroidectomy for exophthalmic goiter, there is not an immediate return of the basal metabolism to normal, a state of hyperthyroidism still persisting over at least several weeks and often longer. In the case of thyrotoxic adenomata a normal level is reached in approximately seventeen days. In this connection, it might be interesting to note that according to H. S. Plummer,⁹ "after the administration of a single dose of thyroxin sufficient to bring the basal metabolism to normal, the physiologic status of a thyroidless patient becomes normal in from ten to twelve days, remains approximately normal for ten days, and returns to the pre-existing status in from five to seven weeks."

In a consideration of the symptoms of exophthalmic goiter, too much emphasis should not be placed

on the text-book cardinal symptoms; namely, tachycardia, exophthalmia, weight loss, nervousness and tremor. While having a definite significance and while being a usual accompaniment of this disease, they are by no means diagnostic.

DuBois, in his paper on exophthalmic goiter, says: "Exophthalmic goiter stands out as the disease of increased metabolism, and the increased metabolism stands out as the chief symptom of hyperthyroidism. The determination of heat production seems to afford the best index of the course and severity of the disease. There was great need for some purely objective test in hyperthyroidism to indicate the effect of treatment."

Exophthalmos is, to be sure, a very important finding and when present, especially with other symptoms, there is little room for doubt. However, many patients with exophthalmic goiter never develop exophthalmos, it being present in approximately only 60 per cent of cases. Tachycardia, nervousness and tremor are so commonly present in neurasthenia that they have little diagnostic importance, except as confirmatory evidence. There is a small percentage of cases in which an evident tachycardia is not present, at least in the sense that the pulse rate is above what we recognize as normal.

W. A. Plummer¹¹ has emphasized the importance of a feeling of sustained warmth as well as a history of ravenous appetite. I wish to re-emphasize these and other symptoms also brought out by W. A. and H. S. Plummer, which are almost diagnostic in themselves.

A feeling of sustained warmth is one of the most significant symptoms and is practically always present. When asked whether or not the patient feels abnormally warm in an average comfortable temperature, the answer is in the affirmative. Further questioning reveals the fact that this abnormal heat is not transient or as hot flashes, but permanent, measured not in terms of a few minutes or hours, but over a period of weeks or months. This feeling of abnormal heat is quite natural when one considers the increased metabolism together with the open periphery. The latter is evidenced by the low diastolic blood pressure and the resultant increased pulse pressure, another important finding in exophthalmic goiter.

A history of ravenous appetite is extremely suggestive. There are only two diseases, namely, exophthalmic goiter and diabetes mellitus, in which

weight loss occurs in spite of increased food intake. A ravenous appetite is present at some time during the course of the disease in practically all cases. It usually requires close and repeated questioning, not only of the patient, but also of his family, to elicit this symptom. This is, as is well known, a very uncommon finding in the neurasthenic, who quite the contrary complains of a poor appetite.

Weakness of the quadriceps groups again is also a very suggestive symptom. Although generalized weakness is practically always present the quadriceps muscles are affected all out of proportion to others. This manifests itself as an inability on the part of the patient to step up a high step without the use of the hands, or quite often even without assistance. The exophthalmic goiter patient, however, is not aware of this weakness until she actually makes the attempt, being imbibed with an unusual degree of confidence which persists in spite of repeated failures. The neurasthenic, on the other hand, attempts the same task with reluctance and a foreboding of failure, only to find that when finally attempted it is easily accomplished.

Other symptoms, such as palpitation; dyspnea, vomiting and diarrhea; generalized loss of strength; headache; abnormal sweating; pressure and fullness over the thyroid; choking spells, etc., are usually present but individually or even collectively are not diagnostic.

Symptoms which are present one day and absent the next are not those of exophthalmic goiter, the latter presenting symptoms which are constant and sustained over a period of weeks or months.

A persistent tachycardia with or without cardiac dilatation, the presence of a thyroid which has a granular feel, and especially the occurrence of thrills and bruits over the superior thyroid vessels are very common findings. Thrills and bruits occur in 60 to 80 per cent of cases.

Where the bruits are louder over the inferior thyroid vessels, they have no diagnostic significance, being quite commonly observed in neurasthenics in this location. Bruits, which have a variable intensity, becoming practically inaudible at times, point also to a functional basis.

Pulse rates of 120 or thereabouts, observed in patients in the office, are very common and when found together with an enlargement of the thyroid a diagnosis of hyperthyroidism is often made, only to be shattered the following day by the presence of a normal pulse rate and normal metabolic reading.

Neurotic individuals are especially prone to develop a rapid pulse which may be present repeatedly on examination, and its true rate in occasional cases being manifest only during sleep. A pulse rate of 80 to 90 is in certain individuals quite within normal limits.

The presence of an increased temperature in a patient with hyperthyroidism should be explained on the basis of an associated infection, most commonly a follicular tonsillitis, rather than on the basis of an accompaniment, of the disease, it being, in spite of the most marked metabolic increase, a condition free from fever.

Basal metabolic readings have an even greater field of usefulness in the determination of the presence or absence of hyperthyroidism in adenoma or nodular thyroids. Here one must rely mostly on subjective symptoms for the clinical differentiation, although cardiac involvement, with increased systolic and diastolic blood pressures, as well as a longer and more gradual course, is commonly present in the hyperfunctioning type. Exophthalmos, as well as thrills and bruits, is absent in these patients unless there is an associated pathological change in the thyroid as is found in exophthalmic goiter.

The average age at which these goiters develop is about twenty-two. An interval of approximately sixteen years occurs before toxic symptoms develop.

This type of goiter was first tentatively designated by Plummer as "toxic non-hyperplastic goiter," then "toxic adenoma," and now "hyperfunctioning adenoma."

The metabolism test affords great aid in the choice of treatment to be pursued. However, in this particular it should be utilized only in conjunction with daily observation of the patient with especial reference to pulse rate, tremor, nervousness, cardiac involvement, appetite and previous weight loss and in no case should it be used as an absolute guide as to the proper measures of treatment. By the latter, I refer especially to ligations and thyroidectomy, which will be discussed by another member of this symposium.

According to Crile¹² the metabolism test is of little value as an indicator of what to do. This I think should be modified and as before stated it should serve as one of the very valuable adjuncts in the preoperative regime.

In closing I wish to again emphasize the importance of the metabolism test, especially as it concerns thyroid work, but also as it applies to other fields of investigation. Its scope is broad, and under proper conditions it stands alone amongst laboratory procedures in the accuracy of its results and in the diagnostic information which it affords.

ARGUMENT IN FAVOR OF THE REDUCTION OF TAX RATE ON EARNED INCOME

The provision of the proposed revenue law that makes the rate of taxation on earned income less than the rate on income from investments, speculation, etc., is new. The benefit thus conferred is to be extended to all taxpayers with earned incomes, and the physician is to be benefited merely as a member of the income-earning group. The concession in favor of earned incomes is based on the fact that taxation on an earned income is taxation on the productive activity of the taxpayer and tends to discourage such activity and that, since the productive activity of the taxpayer may be diminished or destroyed at any time by personal disability and is certainly destroyed by death, it is entitled to special consideration in the determination of the tax rate. The concession in favor of earned incomes has been recommended by the Secretary of the Treasury, but unless those who are to be benefited by it unite in an effort to make their position clear, the secretary's recommendation may not receive favorable action by Congress.

THE VALUE OF BASAL METABOLISM IN A GENERAL SURGICAL PRACTICE*

T. L. CHAPMAN, M.D.

The Duluth Clinic
Duluth

As a premise to any estimate of the value of taking a basal metabolic rate, the scope of its indications must be extremely well defined. The studies of Boothby and many other investigators have seemed to justify the conclusions that in actual practice about 95 per cent of all abnormally increased basal metabolic rates are due to hyperthyroidism, either of exophthalmic goiter or of hyperfunctioning adenoma of the thyroid, providing febrile states are eliminated, and proper conditions essential to physical and mental repose and the various necessary inactivities and inhibitions are complied with. This will leave, then, in this class of high rates, a very small percentage due to such diseases as acromegaly in its active stages (hyperpituitarism) and, at a lessened height of rate, essential hypertension, pernicious anemia, leukemia and diabetes, and possible some other diseases not yet investigated.

Lowered rates are found in the largest percentages in myxedema of varying grades of development or arrest, and also inanition from prolonged fasting or restricted food intake, such as in stricture of the esophagus or cardia-spasm. These bounds then, would seem to include particularly all the diseases in which extremes of basal rates occur, and the sincerity and thoroughness of the investigations have apparently established the tests as certainly valuable in their field.

Of first importance, then, in surgical practice, are basal metabolic rates in the diagnostic estimates of goiters. This general dictum will apply, at some points, to all forms of goiter, giving positive or negative information that may be of prime import. In exophthalmic goiter it is sometimes necessary that the final weight in diagnosis may be almost exclusively in the finding of an increased metabolic rate. The well known complex of symptoms may be so nearly absent, so rudimentary, undeveloped

*Read in symposium at the annual meeting of the Minnesota State Medical Association, St. Paul, October, 1923.

or masked that this laboratory evidence may be essential. In an instance in which exophthalmos is absent, the thyroid not palpably enlarged, the tremor slight, and the other subjective symptoms more or less minimized or concealed (and these conditions may obtain in an active state of the disease), a basal metabolic rate must form a most important part of the evidence in the diagnosis. The presence of fluctuations of malignity in this disease, the recrudescences and remissions, may all be traced accurately by basal metabolic estimate.

In hyperfunctioning adenoma also, the importance of a knowledge of the basal rate is paramount diagnostically. While in this disease the heights of increase are not so great as in active exophthalmic goiter, there is always an increase over a normal rate, and this is usually sustained and progressive and is not characterized by the remissions and gross range that are a part of the natural history of most cases of Basedow's disease. On the other hand many features in diagnosis of toxic adenoma are indefinite and difficult to attribute to their real origin in the goiter, and may be easily accredited to spontaneous myocardial incompetency or nutritional and occasionally senile changes, unless a basal rate is taken and its evidence properly evaluated. In fact by no other single method of examination can the diagnosis in this disease be so definitely determined, or its severity so certainly recognized.

A pre-eminent field for diagnostic differentiation by the basal metabolic rate, is the not unusual type of case in this part of the country, that presents a goiter and a host of more or less indefinite nervous and circulatory symptoms, but without typical or palpably significant changes in the thyroid, perhaps, besides, in an unusual decade of life for thyroid toxicity to occur. Much morbidity and unhappiness have resulted from ill advised surgery and foolish prohibitions of normal activities in this type, where absolute diagnosis has not been made by laboratory methods, and where an incorrect conclusion has led to the belief of severe thyroid disease and more or less vigorous treatment instituted upon this false basis. The large number of patients with colloid goiter and coincident nervous circulatory peculiarities can be catalogued on a more certain diagnostic basis than ever before by means of the basal rate readings.

In some of the hypofunctioning thyroids the

symptoms may be incomplete and inconclusive and ordinary clinical judgment fallacious. The extreme grades amounting to myxedema are sufficiently striking and pointed to make diagnosis certain, but between these very low grades and a normal function, are many stages of the disease that are made possible of effective identification and treatment, by a basal metabolic test only.

Next to differential diagnosis the most important service furnished the surgeons by the use of these estimates, is in the control of treatment of thyroid disease. A lowered rate after a severe and medically treated exacerbation in a patient with exophthalmic goiter, will indicate to the surgeon the favorable time for a partial operation that will permit an eventual later cure of the disease and security and farther decline of the basal rate, to the patient, in the meanwhile. Still again the rate will be informative as to whether sufficient of the gland has been removed so that cure will result, or whether still another partial removal will be necessary. Conversely, when by operative error or by incompetence of the part of the gland remaining to the patient, a degree of hypothyroidism ensues, its scope and limits may be accurately set, and treatment by the thyroid hormone gauged to the essential requirements.

The securing of a basal rate of any given height in a case of goiter does not in itself indicate operability or its reverse. It is impossible that any surgeon should determine that at a certain point, this or that operation is indicated, or is feasible or safe. As is well known, some types of individuals endure disease conditions much better than others. So, at the same known height of basic metabolic rate, one patient may have terrific tachycardia, gastro-intestinal disturbance and uncontrolled terror from extreme nervousness, where another patient with an equal metabolic rate may be taking his nutrition amply, have a reasonable pulse rate, and be of excellent morale, upon the whole, in spite of his disease. In the latter case certainly at least partial operation could be offered with confidence, whereas any operative procedure in the first instance would almost surely result in disaster. A high rate alone is not an index of the degree of disability, and operability must be indicated, or not, from the whole picture of morale and other clinical findings of probable strength and resistance.

THE TOTAL AND BASAL METABOLISM IN EXOPHTHALMIC GOITER*

WALTER M. BOOTHBY, M.D.

Section on Clinical Metabolism

Mayo Clinic, Rochester, Minnesota

As emphasized by the preceding speakers in this symposium, the basal metabolic rate is exceedingly valuable in the differential diagnosis of diseases of the thyroid, and also in measuring the intensity of the hyperthyroidism. Unfortunately, all practitioners are not in a position to obtain accurate determinations of the basal metabolic rate. However, as the total metabolism in twenty-four hours is increased to an even greater extent than the basal metabolism, the former can be used as a diagnostic point, and the variation in weight as an index of the course of the disease and the patient's condition; a gain in weight indicates that the patient is doing well, while continued loss of weight suggests that the patient would not successfully withstand an operation.

In detailed studies we have found that persons with exophthalmic goiter or adenomatous goiter with hyperthyroidism, if left to their own inclination, eat from one and one-half to three times as much food as normal persons under the same conditions of rest or work. It is, of course, impossible in general practice to make an accurate study of the food intake. For diagnostic purposes, however, it is sufficient to learn, by direct questioning, whether the patient is eating more than usual, at the same time lying down a greater part of the day. Patients will say that there is nothing the matter with their appetite, and that they are eating more than normally. The significance of even an apparent slight increase in the amount of food taken is of particular importance if, at the same time, the patient is losing both weight and strength.

Often in cases of exophthalmic goiter, and but rarely in cases of adenomatous goiter with hyperthyroidism, an estimate of the total metabolism by the food intake is complicated by the occurrence of gastro-intestinal crises of nausea and vomiting. As the physician may be called now for the first

time, he should, on finding an increase in pulse rate with or without evidence of cardiac decompensation, inquire into the quantity of food taken in the few weeks preceding the onset of the crisis, which will reveal an increase in the consumption of food, accompanied by more or less loss in weight. If, however, the food intake has been restricted voluntarily by the patient, or on the orders of the physician, evidence of the increased metabolism is obtained solely from the rapid loss of weight. During a period of gastro-intestinal crisis with vomiting, or medical restriction of the food allowance, the patient may lose one pound a day. This is readily explained by the fact that these patients burn from 4,000 to 5,000 calories each day, and if no food is taken, they must burn their own fat at the rate of 400 to 500 gms., or approximately 1 pound of fat each day. Under these conditions, symptoms of acidosis, at least of mild acidosis, are superimposed on the true symptoms of the crisis. It is well known that with starvation, even in normal individuals, a mild condition of acidosis develops as soon as the carbohydrate reserves are exhausted; when the metabolism is increased, as in cases of exophthalmic goiter, a degree of acidosis equivalent to that of a normal person starved for three days may develop in twenty-four hours. In the crisis of ophthalmic goiter, a condition of low blood sugar may develop, accompanied by acidosis; although this is secondary, it forms a link in the vicious circle aggravating the symptoms, and should be avoided. Carbohydrates, therefore, are absolutely essential, and must be given by rectum if they cannot be retained by mouth. The widespread idea that restriction of food is beneficial, is erroneous. Several years ago a trial of a restricted diet was made at the Clinic. Patients on this diet failed to do as well as patients on a high caloric diet after this was adopted as a consistent line of treatment.

Until about two years ago, no specific treatment was known which would control the gastro-intestinal crises of exophthalmic goiter. During the last year and a half H. S. Plummer has demonstrated positively, that such crises can be stopped by the administration of Lugol's solution. The administration of from 30 to 60 drops of Lugol's solution for three or four days, then 10 drops daily, has invariably controlled all the cases of gastro-intestinal crises in exophthalmic goiter that have come under observation in the Mayo Clinic since the method of treatment was instituted. The effect of Lugol's so-

*Read before the Minnesota State Medical Association, October 12, 1923, St. Paul.

lution in cases of exophthalmic goiter is quite as comparable as a life-saving measure and quite as striking and dramatic, as is the effect of Insulin in cases of diabetic coma. Besides controlling the gastro-intestinal crises Lugol's solution ameliorates the entire clinical picture of the exophthalmic goiter syndrome in a very large proportion of patients. Direct evidence of this is the regained appetite, and the coincident reversal of the weight curve from rapid loss to a slow but steady gain. This improvement is accompanied by a reduction in the basal metabolic rate. For from three to six days after giving Lugol's solution for the first time, there is no change in the basal metabolic rate; on about the eighth day there is a sharp drop in the basal metabolic rate, averaging from 20 to 30 points, sometimes exceeding this amount. The drop is most marked in the acute severe cases, less marked in cases of several years' duration, especially if the thyroid gland is rather large, and firm in consistency.

Kocher has repeatedly warned against the indiscriminate use of iodine in the treatment of goiter. This warning should be heeded because iodine in any form is very likely to change adenomatous goiter without hyperthyroidism to adenomatous goiter with hyperthyroidism; likewise it may increase the intensity of a mildly hyperfunctioning adenomatous goiter. Therefore, before Lugol's solution is used, a correct differential diagnosis must be made.

The use of Lugol's solution in cases of exophthalmic goiter before operation has decreased the intensity of the postoperative hyperthyroid reaction so much that preliminary ligations are needed less frequently, and at the same time there has been a marked lowering of the surgical mortality rate. As Pemberton has reported, the surgical mortality is now reduced to 1 per cent, if based on the number of operations, or to 1.7 per cent if based on the number of patients.

NO SCARCITY OF PHYSICIANS

The decline of the country doctor is not due to the temporary decline in the annual output from the medical schools, or a scarcity of physicians in general. This country, indeed, has a generous supply. In 1921, as shown by reliable statistics, there was one physician in the United States for every 726 people, as compared with one physician for every 1,041 people in the British Isles in the same year; and, just before the World War, one to every 1,940 people in Germany, one to every 2,020 people in Austria and one to every 2,824 in France.—*A. M. A. Bulletin, Dec., 1923.*

OBSTETRICS AND THE GENERAL PRACTITIONER*

MARTIN C. BERGHEIM, M.D.

Hawley, Minnesota

In presenting this paper I feel that I shall not be able to give you much that is new, but I have made an attempt to summarize, as briefly and clearly as possible, those underlying principles that should be adhered to by every physician who does obstetrical work, whether he be specialist or general practitioner. It will apply particularly to those in general practice, and especially to those practicing in the country districts. First, because these men have, as a rule, been slow in adopting the new and improved methods in obstetrics; second, because these are the men who do the great bulk of our obstetrical work; and third, if the many advancements that have been made in obstetric practice in recent years are to reach the big majority of the people they must be carried out by the general practitioners.

I shall limit my remarks, not to the discussion of any special phase of obstetrics, but rather to the general management of the obstetrical case from the time of gestation through the puerperium, pointing out the importance of prevention, if possible, of abnormalities and pathologic conditions by careful observation and treatment during the prenatal period, and the detection of existing abnormalities and early treatment of same. I shall, likewise, touch upon the proper conduct of labor; the care of the child during and after delivery; and the care of the mother during the puerperium.

Obstetrics and infant care is a timely topic. Congress in 1921 recognized its timeliness and its importance when it passed the Sheppard-Towner Act, which is "An Act for the Promotion of the Welfare and Hygiene of Maternity and Infancy." The Children's Bureau at Washington, The American Child Hygiene Association, and other associations, have been organized for similar purposes, and all over the country, especially in the larger cities, clinics have been organized for prenatal care. The one great object of all these organizations is to reduce maternal and infant mortality, to reduce maternal and infant morbidity, to relieve the suffer-

*Presented before the annual meeting of the Minnesota State Medical Association, St. Paul, October, 1923.

ings and hardships of motherhood, to strive for a healthy and vigorous offspring, and to be mindful, not of the period of gestation and delivery alone, but of the years that lie ahead, so far as the physical welfare of the mother and child are concerned.

The great aim of medicine, in general, is to prevent ills, to cure ills, to alleviate suffering, to preserve and prolong life, and to promote through education and otherwise the welfare of humanity from the standpoint of upbuilding and preserving health. As obstetrics is the most important phase in medicine that a physician meets with, surely his aim in doing obstetrical work must be nothing less.

The maternal mortality rate in the registration area of the United States, at large, is 6.8 per 1,000, while the bureau of the census on mortality statistics shows that over 86,000 infants less than two weeks of age die annually as a result of conditions existing before they were born, or of injuries and accidents at birth, and 100,000 are still-born.

In 1920 there were in the U. S. A. 16,320 maternal deaths from puerperal causes, and 5,616 of these were due to puerperal septicemia. De Lee estimates that 8,000 mothers die annually from puerperal infection, and he speaks of puerperal infection as "a humanly preventable disease"—preventable, as can be seen from the fact that well conducted maternities frequently care for thousands of cases in succession without a single fatality. In maternal death rate the United States ranks twentieth in the list of civilized nations.

The obstetric dispensaries of the large cities of our own country, as well as those in the cities of foreign countries, care for the mothers in their homes at the time of delivery, often amid the least favorable hygienic conditions imaginable. And, yet, these dispensaries, too, care for thousands of cases successively without a fatality. And the prenatal care of the maternity hospital or the obstetric dispensary can be carried out by the general practitioner, and the aseptic technic at the time of delivery can be carried out by him at the homes, even the very poorest homes. And where this has been done the results have been most admirable. The maternal and infant mortality rate among those cases managed by the general practitioners is considerably higher than that in the maternity hospitals and obstetric dispensaries. The deaths among child-bearing women can be reduced by at least 50 per cent with the proper care during the prenatal

period, during the delivery, and during the postpartum period.

The prenatal clinics of the city can hardly be maintained in the country districts, but the principle of these can be carried out by the family doctor. But the family doctor must be willing to spend a little extra time and effort in so doing. A regularly licensed physician should be in charge of every obstetrical case, and the old idea of seeing the patient at the time of delivery only and then arriving at the bedside only after the perineum is bulging and the head about to deliver is obsolete and should be ancient practice. The patient should be seen just as soon as she realizes that she is pregnant. And she should be given the benefit of every modern advancement in obstetric care throughout gestation. It is a slow process to have any reform in medicine accepted by the laity. But, as a rule, all mothers are desirous of good health and healthy vigorous offsprings, and time and persistent effort will teach the mothers to come to the doctor for information, and to come early. Mothers are beginning to recognize good obstetrics and they are beginning to demand what is their just right in this respect.

Every mother bearing children deserves the best care that the medical profession can give, and this should be rendered from the time gestation takes place until after the puerperium. The careful prenatal care given the mothers at the prenatal clinics of the city can be given fully as well, by the family physician, to the mothers in the country.

To a great majority of the people prenatal care is a new phase in medicine, and it takes time and effort to educate them to realize its value. But the barriers are clearing gradually. In late years one of the greatest factors for good in educating the public has been the county nurse, and in conjunction with her work the distributing of the valuable literature published and sent out gratis by the State Board of Health and by the Children's Bureau at Washington. Among the publications that I make most frequent use of are the monthly prenatal letters sent to expectant mothers by the State Board of Health; "The Care of the Baby," by The United States Health Service; "Prenatal Care" and "Infant Care," by The Children's Bureau at Washington, and "Motherhood," by The American Child Hygiene Association. And in most of the homes this literature is carefully studied.

Prenatal care is the basis of good obstetrics.

According to a statement made by Dublin in 1920 the maternal and neonatal mortality in New York City and Boston has been reduced more than one-half as a result of intensive prenatal care. And this work as it is conducted at the clinics of most of our large cities can be carried out in the country districts. Maintaining a clinic would be unnecessary as well as impractical, but the care that the clinic affords can be given by every conscientious practitioner. The principle of all prenatal care is, first, to care for the mother, and, second, and fully as important, to educate the mother. The careful conduct of labor, employing the best of technic and observing all rules of asepsis and antiseptis, is important, and this is a great triumph for preventive medicine. But prenatal care is of even greater importance. Guide a mother safe and

sound up to the onset of labor and the battle is more than half won. Our only hope in the management of the toxemias of pregnancy, deformed pelves, etc., lies in the conscientious and intelligent management of the patient prenatally.

The expectant mother must come to the physician early, and at this first visit a complete physical examination should be made. The teeth, the organs of digestion, the chest and cardio-vascular system, the kidneys, the breasts and the nipples should be carefully examined. A vaginal examination should be made, and the common pelvic measurements should be taken to determine whether the case falls into the normal group or is one of the occasional abnormal pelves that will require special attention later in pregnancy. At this first visit, too, the pregnancy record should be filled out.

Note: The record cards used for the puerperium and for the labor are 4 inches by 6 inches in size. The record of the puerperium is kept on one side of the card and the labor record on the other side.

Careful record should be made of the patient's menstrual history, the patient's previous pregnancies, previous labors, previous puerperiums, etc. The physician can readily devise his own record card for this purpose.

If at this first examination everything is found normal the patient is instructed to return at least once a month up to the seventh month. A definite date is set for her return. At these visits the blood pressure is taken, and the urine examined, and an inquiry made into the patient's general condition. If the patient is unable to come in from the country, because of the weather or the roads, she is given a bottle in a mailing case with a preservative in the bottle, and the specimen is mailed in.

From the seventh month on the examination is made every two weeks, or even every week if thought necessary. The patient must at once report to the office if any untoward signs or symptoms develop, such as headache, dizziness, eye symptoms, abdominal pain, swelling of the feet, puffy lids,

etc. The most careful attention is paid to the care of the breasts in order that the mother may nurse the baby if possible. The importance of breast feeding is impressed upon the mother.

Considerable freedom can usually be allowed in the diet during pregnancy. Any sensible diet that was suitable to the mother before she became pregnant will in most cases be suitable during gestation. Foods that cause digestive disturbances should be avoided during this time as well as at other times. Within the bounds of good sense the mother can safely follow the dictates of her appetite as to her choice of foods. Certain general principles, however, must be kept in mind: first, the accumulation of waste products in the body causes numerous minor as well as some of the more serious ailments of pregnancy. The mother must throw off the wastes produced by the fetus as well as those produced by herself. The excretory organs—bowels, skin and kidneys—must therefore be kept in the best possible condition. It is most

Note: The cards used for the general physical examination and for the pregnancy record are 6 by 8 inches. The upper half is used for the physical examination and the lower half for the pregnancy record, while the back of the card is used for the pre-natal records of the urine, blood pressure, treatment, etc. This card is folded along the middle and with the other record cards can be filed in a 4x6 filing case.

important that liquids form a large part of the diet during pregnancy, as these aid the excretory organs in eliminating the body wastes. The patient should take at least six glasses of water and an equal amount of sweet milk, buttermilk, soups, cocoa, and chocolates, combined, during the twenty-four hours. Second, a laxative diet must be adhered to in order that constipation and intestinal stasis may be prevented. Third, the diet must have the necessary nutritive value and be well balanced that it may keep the mother in good strength and health. A general rule regarding the mother's diet, then, would be: Large amounts of liquids and fresh fruits and vegetables, and small amounts of meats and other proteins, the latter not to be taken more than once a day. Several lighter meals a day are to be preferred to three heavy ones, and a glass of warm milk at bedtime is to be recommended.

General information is given the mother regarding dress, bathing, exercise, and preparations for delivery (that is, the supplies needed for herself and the baby at, and after, the delivery). She is told what she may expect during pregnancy and delivery. Especially in primipara do we find much anxiety and worry, and these should go to the doctor for information, rather than to relatives and friends.

An abdominal and vaginal examination is made two weeks before the delivery to make sure of presentation and position, and thus vaginal examination at the time of the delivery is usually unnecessary.

If a physician has succeeded in guiding the patient safe and sound up to the onset of labor the battle is more than half won. But it is by no means over. It is in the delivery room that one must exercise exceptional care and use his best technic. The careful aseptic and antiseptic technic used in the outpatient departments of our large hospitals, and in the obstetric dispensaries in the cities, during the time of delivery, can be practiced as well by the man in general practice.

There is a growing tendency for mothers to go to the hospitals to be confined. In the cities, especially among the well-to-do, this is an easy matter. When the labor pains set in an ambulance can be called and the patient is in the hospital in a few minutes. In the country districts it is quite different. Even in the city there are many mothers who cannot go to a hospital to be delivered. This is even more true in the country. In fact very few

of the mothers in the country can conveniently be taken to a hospital; hence, we must bring the hospital to her. Furthermore, I feel that the mother belongs at home at the time of confinement. And whether she is at home or in the hospital she merits the same careful attention.

When called to a case it is better that the doctor arrive several hours ahead of time than that he arrive only ten or fifteen minutes before the baby is born. He can do better obstetrics and it saves the mother and the rest of the family a good deal of worry and grief. If done conscientiously obstetrical work is the hardest work that a physician encounters, and it is also the most important. When called to a case he must, for the time being, forget about his other work. If too busy to give the necessary time and careful attention to a case he better not take it, but turn it over to someone who is willing to take the time.

In the country and in the village, as in the city, the doctor comes to a great variety of homes. It is sometimes against odds that one must work in the delivery chamber. And it is not always possible to carry out one's aseptic hospital technic to the *n*th degree. But, whether the homes be rich or poor, one thing is certain—one can have the use of fire and water and soap. And the proper use of these goes a long way in doing good obstetrical work in the delivery chamber. Add to these a couple pairs of good rubber gloves and a finger-nail brush and one has the major part of his necessary equipment. And, if one combines with this equipment good judgment and an endless amount of patience and "watchful expectancy," and abstains from interference of every kind, he is doing a great deal toward reducing maternal and infant mortality.

In my obstetrical bag I carry everything that is needed for any ordinary case, as well as the things needed for any abnormality that can possibly be handled with safety outside the hospital. This equipment includes among other things an ample supply of sterile linens. Besides the linens done up in smaller bundles and which are carried mainly for emergency use, I have my so-called obstetric bundle, which contains the following articles: Two large sheets, two doctor's gowns, one pair obstetric stockings for the mother, a dozen towels, dressings for the cord, tape, and a few dozen gauze sponges. These bundles have previously been carefully wrapped and sent, ten or twelve at a time, to a

nearby hospital, where they have been sterilized. When I arrive at a case the bundle is ready for immediate use. I also carry two six-quart basins in which I boil water for lysol and bichloride solutions, and one four-quart basin which is boiled with my other instruments. This sterile basin is used for receiving the afterbirth.

As I said before, if a vaginal examination is made two weeks before labor sets in, it is very seldom necessary to do a vaginal examination at the time of delivery. And by avoiding vaginal examination at this time a great source of danger from infection has been eliminated. When labor sets in a careful examination should be made in every case, but this should be abdominal and rectal. I find the necessity of doing vaginal examinations in less than one out of twenty cases. There is no time lost in making rectal examinations and time is often valuable. A non-sterile glove lubricated with vaseline is all that is needed. No matter what precautions are taken in doing a vaginal examination there is ever the danger of infection, as the vagina and entrites reek with virulent bacteria of many kinds. And once a vaginal examination has been done abdominal section and pubiotomy, if later found necessary, are out of the question.

In preparing the patient for the delivery the pubis and labia are clipped and washed with soap and water. A rubber pad covered with a clean sheet is placed underneath the patient.

Shortly before the end of the second stage the vulva, pubis, lower abdomen, medial sides of the thighs, the perineum, buttocks, and anus, in the order named, are painted with half strength tincture of iodine. The doctor sterilizes his hands and he places a large sterile sheet under the patient. Sterile stockings reaching to the hips of the mother are used, a large sterile towel is placed on the abdomen and a folded towel over the vulva. The doctor again sterilizes his hands, and puts on sterile gown and gloves. For this work the hands and forearms are sterilized as for a major surgical operation. One basin of a 1 per cent lysol solution and one of 1:1500 bichloride solution are at hand for frequent rinsing of the hands. An attempt must be made to keep the field just as sterile as if it were a case of major abdominal surgery, and the patient must be handled with just as much consideration and care. Obstetrics rightfully belongs in the class with surgery, and the parturient woman

deserves, and she should enjoy, the same careful consideration that is enjoyed by a case in major surgery. The hands cannot be made absolutely sterile, nor can the vaginal tract and the vulva be made sterile. Hence undue examination and interference must be avoided. The environment in general must be as clean as possible and the doctor and the patient must observe the most rigid principles of asepsis and antisepsis. When these precautions are observed one is doing as much for the protection of the mother as can be done in a well equipped hospital. To be sure, in spite of all one's care, the bed and sheets and stockings will soon be more or less contaminated by the mother, especially in long drawn out labors. But, nevertheless, they give a great degree of protection, and, furthermore, the abdominal towel and the vulvar towel can be frequently replaced by sterile ones, and these towels only are touched by the physician's hands throughout the delivery. The vulva and the perineum are wiped off frequently with sterile sponges soaked in 1:1500 bichloride solution.

It is when we apply promiscuously the newer methods for shortening the second stage of labor in normal cases that we raise the maternal as well as the infant mortality rate. We co-operate with nature most by waiting and giving her a chance; and if she fails, and we must interfere, our percentage of success will be greatest when we resort to the least radical form of interference possible. Many of the ordinary complications met with during labor will be righted by the process of nature if we watch and wait, and much more safely than if we resort to radical measures of interference. To apply forceps without real indications (that is, failure of the powers, or danger to the life of the mother or the child), or to use pituitrin carelessly, is criminal.

Ether anesthesia is used in all my cases. When properly given it controls the pains perfectly. When the head is about to escape from the vulva the first stage of surgical anesthesia is reached and the head delivered without pain to the mother. At the end of the second stage the mother, if she is a primipera, lies in the Sims position, as perineal lacerations can best be avoided in this manner. During the progress of labor DeLee's head stethoscope is used, and the condition of the fetal heart observed at frequent intervals. Special care must be taken in this respect toward the end of the second stage, and should signs of asphyxia in the

child develop one must be ready for immediate delivery.

The child, as soon as delivered, is placed on a sterile sheet. The eyes are at once wiped dry, each with separate sterile sponges. The sponges may be soaked in the bichloride solution. The mucus is wiped from the mouth, and where there is any indication of mucus in the pharynx and trachea it should be aspirated by means of a catheter. The cord is tied and the stump dressed in a sterile manner like any clean surgical wound.

During the third stage, as in the second stage, one must practice watchful expectancy. Manual delivery, whether by internal or external manipulation, adds distinct risk. The mortality rate resulting from accidents of the third stage is greater than that of the first and second stages combined. One's object must be to avoid post-partum hemorrhage and to deliver the placenta and membranes complete. One must give proper time for the placenta to separate normally and interfere only when necessary. On the proper conduct of this stage depends the uninterrupted puerperium, and the health of the mother in later life may be dependent upon it.

The separation of the placenta takes from fifteen minutes to half an hour. When one is certain that the separation has taken place he may aid the delivery of the placenta in one of two ways: First, the recti muscles may be grasped in the hand and held together above the fundus of the uterus, and the mother told to bear down; or, second, the uterus may be grasped by the whole hand and gently pressed down. If not effective the first time the process is repeated at ten minute intervals. If, after one hour, the placenta fails to come away by this method Crede may be used. At times it is necessary to wait an hour or even several hours for the separation. During this time, of course, the patient must be under observation. I have occasionally waited five or six hours, and I once waited twenty-three and one-half hours; in which case there was no hemorrhage. The placenta came away spontaneously, and there were no untoward symptoms afterwards. By hurrying this stage one interferes with the normal mechanism of separation and expulsion, and this is the commonest cause of retained placentas, in whole or in part, hemorrhage and infection.

If possible the cases should be seen daily for several days after the delivery, and the mother and

the child should both be carefully examined at each visit. Even in the country though the patients be ten or fifteen miles away they should be seen on the third and fifth days post-partum, if roads and weather conditions permit.

I require all my obstetrical patients to report to the office eight weeks after delivery for the final examination of both mother and child. No charge is made for the prenatal care nor for the post-partum calls.

DISCUSSION

DR. J. C. LITZENBERG, Minneapolis: I long ago made a vow that whenever I discussed a paper I would never say: "We are to be congratulated upon listening to the doctor's excellent paper." It is absolutely impossible for me to avoid that, and I must retract. I have never heard a paper in my obstetric experience that has given me as much satisfaction as this one, not because it contains so much of the teaching of the department at the University of Minnesota, but because a man better fitted to tell the general practitioner what he can do has read the paper. I have been invited into the country districts to talk to the doctors about the practice of obstetrics in country districts. That was the subject of the last paper that I read at Alexandria. I overheard some remarks, and I presume many of them were made that I did not hear: "Well, what does he know about obstetrics in country practice?" And I knew that was true. I simply had a theory that the country practitioner could practice good obstetrics in the country, and the fact that he was in the country was no reason why he should not practice it. But that was the theory of the teacher, and many of the men would smile and say: "Oh, well, he has his hospital and he has his nurses and he has his assistants and he does not know anything about our problems."

Hereafter if I am invited to give such a paper in the country districts of the state of Minnesota, I shall tell them to get Dr. Bergheim, of Hawley, a village of about twelve hundred people—and he knows more about the practice of obstetrics in country practice than I ever dreamed of. I have been preaching this gospel for a good many years and I have insisted that it could be done. Now a man who has done it has come before this section and proven it. With Dr. Bergheim's permission his paper will be incorporated in the lectures at the University of Minnesota as a proof that a country practitioner has demonstrated that these things can be done in the country. The country practitioners think I do not know anything about it because I never practiced in the country. And I think they are right. But Dr. Bergheim knows and he is putting into practice in a rural community the principles of as good obstetrics as any city enjoys.

I am having a little difficulty in not waxing overenthusiastic about this. You know when you have suffered and sweat blood over certain things, it does you good to hear your position supported, and especially by a country practitioner in a town of only twelve hundred people where they are getting as good obstetrics—if I may be permitted to say it—as they are in Minneapolis or St. Paul. It is certainly a great satisfaction to me to hear a country doctor preach the doctrine that prenatal care can be carried out in the country, in spite of the fact that they have not the dispensaries.

There is one very significant sentence in his paper, and that is: "Prenatal care and aseptic obstetrics can be carried out in the country as well as in the city." The doctor even mentioned the care of the teeth and the breasts! Who ever heard of such a thing—a country doctor talking about the care of teeth and breasts in country practice! And he has told us just how to do it and do it right.

In closing may I remind you of the doctor in Dixon's novel that was popular a decade ago, "The Leopard's Spots," in which the country doctor was depicted as a man who didn't look upon his practice as a business but as a calling. A man who is willing to give the time, patience and devotion to an ideal in the practice of obstetrics in the country as Dr. Bergheim has been doing is a man who looks upon his profession idealistically, as a calling and not only a business.

DR. W. E. RICHARDSON, Pipestone: May I speak for the country doctor just a moment? I know Dr. Litzenberg didn't mean to slam the country doctor particularly, but he certainly did when he said, "Who ever heard of such a thing—a country doctor talking about the care of teeth and breasts!" I graduated from Rush in 1896, and I have always taught the mothers to be careful of their teeth and breasts.

DR. J. C. LITZENBERG, Minneapolis: I put you in a class with Dr. Bergheim.

THE CHAIRMAN: I think that Dr. Litzenberg in his enthusiasm overstepped a little. I do not think he meant to cast any aspersion on the country doctor at all.

DR. W. A. COVENTRY, Duluth: I have enjoyed this paper very much. Dr. Bergheim has incorporated in it, as Dr. Litzenberg has said, a great many valuable things. One thing that he mentioned in the paper is to my notion very valuable, and I have carried it out for a long time, and that is to have a strictly obstetrical grip in your car or in your office. In fact, I keep one at home and one in the office so that I can always have it handy. In that grip everything that you need for an obstetrical case is sterilized and wrapped in separate packages, so that when you get to the home you do not have to depend upon the kitchen fire

or anything of the kind for your sterilization. You have everything with you. That has been a very great aid.

I did not hear in the doctor's paper anything about the postnatal care. This to my notion is just as important as the prenatal care. The patient should be examined five to six weeks after confinement, and during that interval the patient should have, according to my notion, knee chest position or something on that order, to see that the uterus properly comes back to its right position. If it does not the use of the pessary post partum is a very valuable aid in helping to do so.

DR. M. C. BERGHEIM, Hawley (closing): In answer to Dr. Coventry's remark I might say that I mentioned that I examine the patients eight weeks after delivery, the mother and the child both. I brought that out a little more in the paper that goes in to the publishers, but I had to read more or less of a summary of the paper now.

In regard to the obstetric bundle: as I said, I have everything in this package—everything that is needed for a single case—and this one large package is wrapped several times in sheeting so that it cannot be contaminated. I make up about ten or twelve of these packages and send them to a hospital to be sterilized. They do this free of charge and they are prompt in sending them back. When I come to a case the package is ready for immediate use.

It might be brought out too that this prenatal care adds quite an additional burden to the general practitioner's work; but if you have definite days when these patients return to the office—even if you have from thirty to fifty of them booked up as much as six months ahead of time—you can manage the work very nicely if you have them come on definite days. I tell them that they must not come on Saturdays because those days are full enough anyhow.

I want to thank Dr. Litzenberg for discussing my paper.

"BUSINESS" AND "COMPETITOR"

There seems to be an increasing use by physicians of the term "business," when referring to their individual work in the practice of medicine, and of the term "competitor" when referring to their professional associates. This is unfortunate and unwise. If physicians regard the practice of medicine as a business, certainly the public will so regard it. If physicians look on other physicians as competitors struggling for "business," the public will surely regard all physicians in that light. The consequence will be that physicians and public will soon be employing all the tricks of "business" to gain for these respective groups the financial advantages which they may think are to be obtained from the application of sharp "business" practices.

Medicine is a profession, with traditions and ideals. The real physician is a professional man, who believes in and upholds the ideals of his profession. A profession which forgets its traditions and ideals will quickly cease to be a profession and will degenerate into a business. A true physician is one who is inspired with a "lust for scientific truth" and with an earnest desire to apply the demonstrated

facts of scientific medicine for the good of mankind and to carry its beneficial service to all those who need its ministrations. There is more to him than merely a knowledge of medicine and a college degree. He looks on men of his kind engaged in the practice of medicine as professional associates and brethren. There is no talk on his part of his "business" and his "competitors." He puts a just value on his services to those who can pay and expects and demands payment, after striving to give the very best service of which he is capable. To those who cannot pay, he renders the same sort of service, promptly and cheerfully, without regret that his work will not receive financial reward.

It is easy to see how one not possessed of the qualities of the true physician can look on the practice of medicine as a "business" and consider others engaged in it as "competitors." It is just as easy to see how and why such a member of the profession can and may degrade it in the eyes of the public, until the public comes to look on medicine as a business rather than a scientific profession whose followers are fired with a spirit of helpful service to men.

—A. M. A. Bulletin, Nov., 1923.

CLINICAL FEATURES OF EXTRA-UTERINE PREGNANCY*

THURSTON WILLIAM WEUM, S.B., M.D.

Instructor in Obstetrics and Gynecology,
University of Minnesota

Minneapolis

Pregnancy outside the uterus is a condition of comparative frequency. It may occur in the ovary, peritoneum of the abdominal wall, or any part of the tube. Clinically, we deal almost always with some type of tubal pregnancy. An ovarian gestation is a comparatively rare occurrence (less than sixty authentic cases have been published). A primary peritoneal pregnancy is so rare that all cases have been questioned, although Gröne reports a case in which the fertilized ovum had been implanted upon the peritoneum behind the right round ligament.

Last spring I reported the results of a study of twenty-five cases of extra-uterine pregnancies at St. Mary's Hospital during the years 1921 and 1922, in which ectopic pregnancy entered either in the working or final diagnosis. In this series twenty were operated, eighteen of which the microscopic or macroscopic findings proved to be primarily some type of tubal pregnancy. The other two were hemorrhagic ovarian cysts with free blood in the abdomen. Of the eighteen, fourteen were diagnosed either as ruptured or possible ectopic before operation. Other working diagnosis or diagnostic impressions with or without ectopic were: three threatened abortions, three hemorrhagic or ruptured ovarian cyst, two salpingitis, two pelvic abscess, one acute appendicitis, one acute abdomen with possible perforation in the gastro-intestinal tract, one retroversion of the uterus with metrorrhagia and one abruptia placenta. One case was operated twice within seven months: first a ruptured right tubal, second a left tubal abortion. There were thirteen ruptured tubal pregnancies, five tubal abortions and one secondary abdominal pregnancy of four months' gestation, primarily a right tubal. Pregnancy took place fourteen times on the right. Three had previously been operated for tubal pregnancy on the opposite side. Three died, two on the operating table and the other thirty-six hours after the operation. All three could probably have been saved if timely decision

to operate had been made. The period of gestation, six weeks to four months, averaged nine weeks.

The first and most important factor in the diagnosis of extra-uterine pregnancy is a most careful and complete history. This was generally found to be true in the cases where the pre-operative diagnosis was confirmed by the post-operative findings.

There is a strong presumption of pregnancy when a healthy adult woman, who is usually regular, passes over the expected date of her period by several weeks, along with this develops mammary changes and complaints of morning sickness. (Only in twenty-five to thirty per cent of tubal pregnancies do we find irregular bleeding at or before the time of the first period following conception. This happened in two of my cases, which I will report later.) Polak in a recent study of 307 ectopic pregnancies brings out this point, that tubal pregnancy occurs most frequently where there is a history of previous inflammation of the tube, premenstrual dysmenorrhea or a congenital anomaly. The first symptom of irregular bleeding should put us on our guard. Let us briefly consider the relation of the pathological processes to the physical signs.

FIRST STAGE

Intramural Extravasation or Before Internal Hemorrhage.—Tubal bleeding is due to the unstable position of the ovum owing to the imperfectly developed tubal decidua and erosion of the ovum, which apparently has a pseudo-malignant property of destruction of tissue, into the underlying muscle. This intramural extravasation produces such ovular unrest as to cause tubal distention and peristalsis, consequently the uterine contractions with bleeding and the milder colicky pains which precede the more severe pains of the passage of blood into the peritoneal cavity. The growing ovum with the bleeding into the tissues causes the tenderness over the distended gestation sac.

The impregnated ovum produces the amenorrhea, stimulates a decidual reaction throughout the mucous membrane of the tube of a group of cells, which is not a true decidua at the site of implantation, although it may be found in other parts of the tube, as well as in the opposite tube. The uterus is enlarged, because of a decidua prepared for the reception of the ovum. Congestion is present, due to the pregnancy, and this accounts for the

*Presented before the annual meeting of the Minnesota State Medical Association, St. Paul, October, 1923.

slight softening of the cervix. It is generally supposed that when the ovum implants itself, it rapidly sinks below the mucous membrane into the underlying muscle; the destructive action of the trophoblast splits the muscle and opens the blood vessels, resulting in a hematoma or an extravasation of blood extending around the lumen of the tube or the length of it. This process is rather slow and inasmuch as we find the same kind of tissues in the uterus and tubes, the peristaltic wave is transmitted to the uterus, resulting in contraction with slight bleeding from the endometrium and mixed with this blood is the secretion from the hypertrophied utricular glands, which, as a rule, does not clot and is a characteristic sign. As the tube enlarges, the increased weight favors a prolapse of the tube into the cul-de-sac.

At this stage on making a bimanual examination, we find: (1) the cervix slightly softened; (2) bloody discharge, which does not clot; (3) cervix very sensitive to motion, due to the peritoneal irritation from the tubal enlargement or its prolapse, and to the reaction of the peritoneum covering the uterosacral ligaments; (4) pulsation of the uterine artery on the side of the gestation is more marked; (5) the uterus is slightly enlarged and may be displaced to one side, because of the tubal tumor; (6) Hegar's sign absent, except there may be softening in the interstitial type; (7) the tubal tumor is rapidly growing and very sensitive, because of the stretching of the peritoneal covering.

SECOND STAGE

After Internal Hemorrhage (Tubal Abortion or Tubal Rupture).—(a) A so-called tubal abortion may be and probably most always is a fimbrial rupture through the ostium or through a break in the tissues by the extravasation of the blood to the ostium outside the mucosa. The hemorrhage into the abdomen in this type is not as rapid and, therefore, attended with less shock. In a large series of cases reported by McDonald, it was stated that when the location of the ovum was noted, it was found in the outer third of the tube in 75 per cent of the cases and in the middle third in 15 per cent. The mortality after tubal abortion 1.6 per cent and the mortality after rupture 17 per cent. It is assumed that a large percentage of the ampullary and fimbrial gestations will end in abortion, many of which are not operated or much less diagnosed.

(b) In a tubal rupture or transperitoneal rupture the period of intramural extravasation may be

less and with only a few preliminary symptoms. The severe intraperitoneal hemorrhage, resulting in shock and collapse, generally is found in this type. The amount and rapidity of the bleeding determines the pulse frequency, drop in blood pressure and the leucocytosis. The effused blood becomes distributed over the general peritoneal cavity and tends to accumulate in the dependent parts; viz., the cul-de-sac and the renal pouches. If the bleeding is slow and the amount small it becomes walled off and we have the encysted type sometimes called a retro-uterine hematocele.

Primary abortion or rupture generally occurs before the eight week of gestation and usually means the death of the ovum, consequently the uterine hemorrhage is increased by the expelling of the decidua, either in mass or piecemeal.

At this stage of internal hemorrhage a differential diagnosis is sometimes hard to make between an ectopic pregnancy and an acute lesion of the abdomen. The history of a possible pregnancy or disturbed menstruation is most important and with it the findings present in the first stage if the patient has been under observation; plus the history of colicky pains followed with a severe sudden stabbing pain in region of the tubal mass; the presence of more or less shock; the peritoneal reaction resulting in a slight elevation of temperature and a moderate leucocytosis should help us to make a diagnosis before the tragic symptoms set in. On vaginal examination, we generally find the uterus displaced forward and elevated; it may be to one side and the rest of the pelvis filled by the effusion of blood, and, in the encysted type, the swelling elastic. It may be doughy in parts and the pouch of Douglas bulging. The encysted type should be diagnosed from (1) an incomplete abortion, (2) an inflammatory effusion, (3) an incarcerated ovarian tumor, (4) and a retroversion of a gravid uterus.

The following case reports are typical of conditions found in this stage:

Case 38,111. Admitted Aug. 14, 1921.

Working Diagnosis.—Ruptured ectopic pregnancy.

Final Diagnosis.—Ruptured right tubal pregnancy.

M. History.—Patient 25 years, married 5 months. Last menstrual period two months ago. Menstruation commenced at ten years; irregular, five weeks and sometimes missed a period; duration three to four days. Last period was normal.

P. C.—Pain in lower right quadrant commenced at 4 P. M., on the 13th; one-half hour later vomited. Saw patient at 6 P. M.

History of Onset.—Patient had noticed during the last week a slight bloody discharge. Had typical symptoms of normal pregnancy with slight nausea and vomiting developing two weeks ago. During the last week has had a few colicky pains and thought that she might possibly menstruate. On the day of onset the patient had felt normal and was doing her usual housework when she was suddenly taken with a sharp stabbing pain in the lower right quadrant.

Examination.—Patient well nourished, with the appearance of shock. Rigidity of muscles on right side. Tenderness general over lower abdomen, but more marked on right.

Vaginal Examination.—Cervix slightly softer than normal; marked pain on pressure; slight bloody discharge; uterus slightly enlarged and to the left. Right adnexa indurated and very tender to pressure. Diagnostic impression at this stage was an extra-uterine pregnancy.

At 8 P. M. I saw the patient again and the pain extended to the right upper quadrant with general tenderness over the abdomen; pain in upper quadrant, suggesting a typical gallstone colic; also, pain between shoulders. Temperature 98, pulse 90, blood pressure 100/70. At 6:30 A. M. the fourteenth, patient was brought to St. Mary's Hospital. Pain very severe and at times intermittent. The blood picture showed the following: Leucocyte count 16,300; hemoglobin 40 per cent; P. M. N.'s 74 per cent; temperature 98; pulse 100. Noon: Temperature 97, pulse 120, blood pressure 130/60. Vaginal examination showed bulging in the cul-de-sac, more marked on the right. At 3 P. M. operation; medium incision, abdomen and pelvis filled with blood, right tube found ruptured in middle third. Both ovaries and left tube found normal. Gall-bladder negative. Blood transfusion (450 c.c.) given as soon as hemorrhage was stopped; right tube removed, usual sutures and no drainage. On the 16th patient passed decidua in mass. There were no complications. Patient left hospital the 27th improved.

Case 40,822. Admitted June 8, 1922.

Working Diagnosis.—Tubal pregnancy (right) or cyst of right ovary.

Final Diagnosis.—Ruptured tubal pregnancy right.

M. History.—Patient 39 years, married; four previous pregnancies, second of which was tubal. Menstruation commenced at 14, regular 30 day; last, April 20th.

Complaint.—Uterine hemorrhage since May 21st; severe stabbing pains on right side, came on suddenly yesterday, was intermittent every three to five minutes, lasted two or three hours. Second attack at 4 P. M. today.

Vaginal Examination.—Cervix softer than normal; discolored, bloody discharge; uterus enlarged, size of two months' pregnancy; induration in right broad ligament, mass felt size of an orange. Left adnexa negative. No pressure in cul-de-sac. Pain present on moving the cervix.

Operation on the 9th.—Medium incision, free blood in pelvis, ruptured right tubal, mass size of small hen's egg, adherent (specimen sent to University Laboratory). Right tube and ovary removed. Usual sutures and no drainage. Patient left hospital June 20th, improved.

THIRD STAGE

Secondary abdominal pregnancy,—in this stage when the ovum survives a tubal rupture or abortion, the diagnosis is much harder to make and next to impossible without a complete history. The findings should show a cervix harder than that of an intra-uterine pregnancy. The uterus may be mistaken for the head of the fetus. A careful examination under anesthesia should be made and the passing of the sound, if necessary, to determine the depth of the uterus.

Let me give the history of one of my cases which falls into this group.

Case 41,753. First admitted Sept. 19, 1922.

Working Diagnosis.—Ectopic pregnancy or threatened abortion. (This patient gives history of previous left tubal pregnancy five years ago.)

History.—Patient 27 years old, last regular period July 2nd. On September 2nd and every day since has had more or less vaginal discharge with blood. Noticed nausea developing about the middle of August. September 4th developed vomiting, which has been almost continuous since.

Examination.—Cervix uteri discolored, soft, bloody discharge. Corpus uteri enlarged, size of two months' pregnancy. Soft and in anterior position. Right adnexa mass felt, doughy. The 20th, blood hemoglobin 88 per cent; leucocytes 9,300; P. M. N.'s 66 per cent; consultation, advised waiting. Patient was in the hospital eight days and gradually improved. Patient kept under observation at home and on the 17th of October uterus appeared symmetrical, patient feeling very much better and had hardly any nausea, although there was a daily show of blood. October 24th, 10:30 P. M., was taken with severe cramps, had indulged in large quantities of food, and on the 26th the patient was having intermittent pain every two to six minutes apart—sent to St. Mary's Hospital with a diagnosis of abruptio placenta and second inevitable abortion. Patient gradually improved until the afternoon of the 28th. Hemoglobin was down to 45 per cent, pelvic examination showed mass extending to umbilicus, symmetrical and a four to five months' pregnancy. Six o'clock patient was in shock, sent to the operating room, pulse 140 and becoming rapidly weaker. Passing a sound showed only depth of about 3.5 inches, cervix fairly firm and immediate laparotomy performed. A mass in the mid-pelvis in abdomen covered by omentum and large amount of bright red blood in pelvis and abdomen. Mass contained four months' fetus, 6.25 inches long and was well protected by omentum and adhesions of intestines. Patient did not recover sufficiently to take blood transfusion, which had been prepared. Patient died before leaving the operating table. Conclusion in this case was that the original rupture had taken place when seen in September and death of fetus did not take place, resulting in a tubo-abdominal pregnancy.

As we progress in the practice of medicine and our experience increases, we are more impressed by our mistakes than by our successes. Anyone

who has experienced the tragic and seen the fatal termination of an extra-uterine pregnancy can have but one answer to the method of treatment, when diagnosis has been made, and that is, operation immediately. Of course, I realize that there may be a few exceptions and I will briefly give them.

1. When a case is seen in the first three months of gestation and the patient is in shock, with the blood pressure low and the pulse thready, one may be justified in waiting until the reaction sets in, which may happen if you see the patient during or following the primary rupture. If there is a history of several sudden and sharp pains, followed by shock, then I do not think that you are justified in waiting. In all three cases that died at St. Mary's Hospital, there had been histories of repeated sharp attacks, followed by more or less shock, and if we wait long enough we will see the patient during her last and fatal hemorrhage.

2. If a diagnosis of extra-uterine pregnancy has been made and the case has passed beyond the seventh month, one may be justified in waiting until the fetus is stronger. An operation should be performed before patient goes into labor. The best method of taking care of the placenta in this type, is to leave it, unless the maternal attachment can be clamped off, as is sometimes found in the pedunculated ovarian type.

In an exsanguinated case give salt solution intravenously and follow with blood transfusion. Do not rely on the salt solution by rectum. I would suggest at the time of the operation that the free blood, found in the abdomen, be citrated and poured back into the abdominal cavity and not transfused, as we know that there is a rapid absorption of fluids by the omentum and peritoneum. Another thing to remember in a blood transfusion following an intravenous injection of salt solution is this, that it is not the quantity of the blood, but the stimulation caused by it that carries the patient over this critical period.

In regard to the advisability of removing the other healthy tube on the presumption that an ectopic pregnancy might develop in it at a later date, the answer should be "no," as there are more babies born following an ectopic than the number of ectopics. As a prophylactic measure in doing pelvic surgery and especially so in the Baldy-Webster, or Gilliam operation, avoid any angulation of the tube.

DISCUSSION

DR. F. L. ADAIR, Minneapolis: The etiology of ectopic pregnancy is still clouded with considerable obscurity, and until we know more of course it will be difficult for us to prevent the incidence of ectopics. Undoubtedly certain physiological facts may be contributory causes to ectopics. This may perhaps be due in some instances to the time of the fertilization or insemination of the ovum.

Necessarily in an ectopic the ovum must be fertilized before it reaches the uterus. Whether it is physiological or not for it always to be fertilized before it enters the uterus, is still open to question. Perhaps in some instances when ovulation occurs late in relation to insemination, the fertilization of the ovum within the tube may be favored, which of course is a prerequisite for the occurrence of any ectopic pregnancy.

The work of Snyder in studying the changes in the tube indicates that the tube undergoes certain physiologic changes which correspond more or less with the changes in the corpus luteum; that is, the changes are more or less chronological. The inflammatory conditions of the tube have been spoken of as a definite cause of ectopic pregnancy. In a series of cases studied by Stein there was evidence of inflammatory conditions in the unaffected tube in about twenty-five per cent of the cases.

In this series he found no prolonged period of sterility preceding the ectopic pregnancy, which of course is an argument against inflammatory conditions being a very potent factor in the causation of ectopic pregnancy. He also stated—which has nothing to do particularly with the etiology, but is of interest in connection with diagnosis—that over fifty per cent of the cases were correctly diagnosed before operation. Following the theory of Sturmdorf, Magid suggests that a chronic endocervicitis is a predisposing factor in the causation of ectopic pregnancy by causing a perisalpingitis, which consists of an inflammation of the cellular tissue around the Fallopian tube. It seems to me perhaps a little more logical to think that the same underlying infection is the cause of both conditions, and that it is not necessarily the result of the endocervicitis.

It is unlikely that we shall soon be in a position to prevent the development of ectopic pregnancies. A thorough understanding of the underlying causes and the possible elimination of these predisposing factors might reduce the numbers of these cases.

The hope in the cases is from early and accurate diagnosis with prompt and effective treatment. A study and analysis of the clinical course and physical findings is of the utmost value. It is this which makes a presentation such as that of Dr. Weum's valuable to the clinician and also to the patients.

DR. A. MACLAREN, St. Paul: There are two points of which I want to speak. My experience in ruptured extra-uterine gestation cases is that abdominal section is necessary in probably ninety per cent of these cases if you are going to save the patient. The mortality in my experience has been in the neglected cases, and the ones that have been allowed to bleed into their own abdomens a number of times and the operation is delayed too long. The tear of the tube with intra-peritoneal hemorrhage very often comes at the time of the first missed menstruation. The fetus occasionally is killed by the tear. Then a pelvic hematometra usually forms in tubal abortion cases.

The first experience that I had, a great many years ago, was in opening one of these pelvic hematometra cases: a small pelvic hematometra, typical history of extra-uterine gestation with rupture and tear opening it. As we know, pelvic hematometra will often go on the formation of a pelvic abscess. If such a case is opened in the early stage of infection, the peritoneum is set on fire and the patient dies of acute septic peritonitis. After the early stage of infection had passed a number of cases were operated upon, by vaginal section and clamping the tube (as was just mentioned) and draining the pelvic hematometra, and the patient recovered.

Now when we open the abdomen occasionally we will find that the patient has had a tubal abortion. I believe that it is almost as reasonable to remove the tube in these cases as it would be to remove the uterus after an abortion. The danger of hemorrhage has passed. You have to deal simply with a pelvic hematometra. One of my patients who had only one tube and ovary was very anxious to have a child, and had a successful delivery after opening and cleaning out the tube as described above.

DR. L. W. BARRY, St. Paul: Ectopic pregnancy is not always easy to diagnose, but of course it is always easy to diagnose after you get in the abdomen. I think the most important factor in the diagnosis or the most important sign in the diagnosis of ectopic pregnancy is spotting. Practically all of the cases—ninety to ninety-five per cent—will give a history of disturbance of menstruation and spotting. They run all the way from two weeks to six weeks or two months, and some time in this interval begin to bleed. Usually the blood is not bright red as it is in the incomplete abortion or threatened abortion, with which ectopic is most usually confused; but the blood is dark and does not clot.

Now once in a while we have an inflammatory tubal condition. Especially where we have a flare-up of an old tubal condition we have spotting. Usually, though, the pain is on both sides and is not one-sided. Once in a while we have trouble in making a diagnosis between an ectopic and an ovarian cyst with a twisted pedicle. They have sudden one-sided pain; they go into collapse, have a slight temperature and slight leucocytosis. Once in a while we have difficulty in diagnosing between an ectopic and incarcerated uterus.

In the treatment of ectopic pregnancy I think the thing to do is to operate as soon as the diagnosis is made. Once in a while, of course, you will be called out in the country, and the patient has not consulted a doctor soon enough to be operated at the opportune time. She is in collapse. What are we going to do? If we have any instruments we should operate. Sometimes we take these patients to the hospital and they die on the operating table. Two of these that Dr. Williams reported died on the table. I think the thing to do is to transfuse before you operate and not afterward. I think it is a very poor plan to trust to salt solution. The patient needs blood now. Pouring the citrated blood back in the abdomen I think is a very good idea. Sometimes it is practically saved anyway, and you can leave it and absorb it without very much trouble. Some put ether in the abdomen—all of which are very good measures.

DR. W. A. COVENTRY, Duluth: I would like to draw the attention of the society to one thing that happened in my practice, and that is a question of induced abortion in extra-uterine pregnancy. Within the last year I have had such a case, she admitting having consulted a physician who committed abortion, or attempted to at least, on two different occasions within a week. The patient had an extra-uterine pregnancy of about three months' duration, unrecognized by the abortionist. The outcome was fatal because the patient had become infected. However, it brings up the point of not depending too much upon spotting, but depending more upon your physical examination and your bimanual examination.

Dr. Barry brings up the point of transfusion before operation. I believe it is better at the time of operation or immediately afterward. I think most of the blood that is put into the patient will be washed out if transfused before operation.

Then there is the question of operating on these life and death cases. You have to operate as fast as you can and do as little as possible. The thing to do is to stop your bleeding, close quickly, and get your patient to bed. Don't bother to wash out blood; don't bother to wipe out the clots; leave them alone. Babcock has made this suggestion: in desperate cases he goes through the cul-de-sac and grabs and clamps the bleeding tube, stopping the bleeding, and getting the patient off the table and into bed, thus not unduly shocking an already badly shocked patient.

DR. V. J. HAWKINS, St. Paul: I haven't very much to say, but the whole thing with tubal pregnancy is to make a diagnosis at once and operate at once, and you will save all of your patients. It doesn't make any difference where you are. If you carry out ordinary asepsis, if you are ordinarily careful, you will save every one of them. You say that is not the right way to get at the question, but this thing of waiting and making all sorts of blood tests is fatal. The diagnosis is practically made every time, on the passage of blood and mucus that does not clot. It looks like coffee grounds, only that it is black. And with the history and the possibility of pregnancy it is safer to open the abdomen in a hundred patients than it is to get down to fine diagnosis. We have had at least twenty cases in the last seven years without a death. One of those cases came to us after they had been told that there was no use

of attempting to do anything, no use to take it to the hospital. Extreme prostration or shock. Put patient on the table, clamped off the tube and removed it and closed her up, and she got well. We didn't make any transfusions or anything of the kind; didn't fool around with anything. Go at it like you did with appendectomy thirty years ago. Go right at it. Fool around and you are going to lose them every time. It doesn't make any difference how they were in the beginning, if you wait to see if that patient is going to die, the patient is gone.

DR. T. W. WEUM, Minneapolis (closing): Dr. Hawkins brought out the importance of not depending entirely on your blood findings. That is fatal, because as I stated in one of my cases, the hemoglobin was up to 88 per cent. There was nothing unusual in her early blood picture. I had seen that patient the afternoon before the blood picture was taken, and she was in shock. At that time I made a definite diagnosis of an extra-uterine. The next morning she was in the hospital. She was smiling and feeling good. And here was her blood count. The examination by another man indicated that it might possibly be an intra-uterine. The family thought there was no harm in waiting, and we waited eight days, and the patient left the hospital very much improved.

Those are the cases that we are fooled on. You have made mistakes; I have made mistakes. But let us profit by our mistakes. To show how easy it is to make a mistake: Last month I operated on a woman who was forty-one years old. Two years ago I had delivered her at St. Mary's Hospital. During the delivery I had felt a large fibroid of the uterus, the size of a hen's egg. There was nothing unusual in her menstrual history afterwards until about two months ago, when she started to menstruate and had an irregular menstrual flow for a period of four weeks. I decided to send her to the hospital. I knew that she had a fibroid, because I had felt it two years ago. She was a large woman, somewhere between two hundred and two hundred and fifteen pounds, and about five feet in height. You know how much you can feel in an abdomen of that size.

With this history of continued spotting and severe stabbing pain in the lower left quadrant on two different occasions and the uterus hard and slightly irregular like a fibroid uterus, I decided to send her in, and thought perhaps we could eliminate the possibility of malignancy by a diagnostic curettage. During the operation I found that the fundus was rather soft on curetting. The softness of the fundus decided what course should be pursued. We went in above and found this small fibroid uterus and also a left tubal pregnancy with free blood in the abdomen.

Now this was right during the time when I was writing this paper, and I should have been prepared, but although I thought of it, I didn't think it was possible. It just goes to show how you have to be on guard. Another thing that I wanted to bring out is that in the cases where you see them in shock, you will find the blood pressure low; and as the blood pressure goes up, say from ninety or a hundred to a hundred and thirty, that is the time to operate, as soon as the reaction sets in, because the clot is going to break again and you will have a second hemorrhage. Operate them just as soon as they make the curve.

A BRIEF REVIEW OF THE VARIOUS PHASES OF EPIDEMIC ENCEPHALITIS IN MINNESOTA FROM 1919 TO 1923 INCLUSIVE. (PERSONAL OBSERVATION OF 340 CASES) *

E. M. HAMMES, M.D.

Associate Professor of Neurology and Psychiatry,
Medical School, University of Minnesota

St. Paul

In the editorial column of the Journal of the American Medical Association (March 10, 1923, p. 696) we read the following: "From the spring of 1920 until recently, there have been comparatively few new cases of epidemic (lethargic) encephalitis in North America, and interest in it has been kept up mainly by the surprising array of its somatic and psychic sequelae. Within the last few weeks, however, reports have come of a large epidemic in Winnipeg, and smaller ones in Connecticut and elsewhere."

The fact that our experience in Minnesota has been at variance with this, and because the 1923 wave of epidemic encephalitis has been more prevalent and more virulent than any previous one, is the main reason for again presenting this subject, about which over two thousand articles have been written in the past few years.

A statistical study, obtained through the kindness of the State Board of Health, reveals that from April, 1919, to July, 1923, inclusive, 295 deaths occurred in Minnesota from encephalitis; 134, or over 45 per cent of which were in 1923. The mortality rate, taken from the literature and from our own experience (a study of 340 cases), is approximately 17 per cent. Accordingly, about 1,735 cases of moderate or marked severity have occurred. And if we add to this number the abortive and extremely mild cases, with not sufficient symptoms to seek medical aid, it can be conservatively estimated that over 2,000 cases have developed in Minnesota alone since the spring of 1919. Judging from the literature, Minnesota has not been involved to a greater degree than the other states in the Union.

This brief statistical study gives us a conception as to the enormous number of cases which have occurred throughout the civilized world since the beginning of this protean disease in the winter of

*Presented before the Annual Meeting of the Minnesota State Medical Association, Oct. 11, 1923.

1916 in Vienna, from where the first cases were reported by Von Economo.

A study of the statistical chart shows that Minnesota has passed through four definite periods of exacerbations. In 1919 the greatest number of deaths occurred during the months of April and November. In 1920 there was a definite increase in the mortality during March—remaining fairly quiescent during the remainder of the year. A similar although greater death rate, occurred during the spring months of 1921. During 1922 the disease remained fairly quiescent, averaging less than four deaths a month. However, in the early months of 1923, a most marked exacerbation occurred and more deaths were reported during the first five months of this year than any two previous years combined. Similarly the number of cases which occurred was greater, the organism apparently more virulent and the disease in many of the fatal cases of shorter duration than during any previous wave.

This marked increase in the number of deaths reported during 1923 is due to three factors:

1. The organism seemed more virulent than at any time previous.
2. Because of the profuse literature on the subject, the medical profession had familiarized itself with the many varied and bizarre syndromes which this disease presents.
3. Some deaths were undoubtedly due either to sequelae or exacerbations in cases previously afflicted with encephalitis.

As is demonstrated in the statistical chart, epidemic encephalitis has shown a definite increase during the early spring period, over 52 per cent of the deaths occurring during the first four months of the year. This is in accord with the Monthly Mortality Rate of New York in 1920, where the greatest number of deaths from encephalitis occurred in February and March, 53 and 57 respectively. Furthermore, there has been a marked rise in the death rate in each subsequent year, 1922 excepted. This is of special interest, for in every known epidemic the virulence of the organism usually abates after having reached its climax. In anterior poliomyelitis, this has been partly attributed to the fact that one attack, even mild, produces immunity, and in all probability many abortive and extremely light cases, unrecognized, develop during an epidemic, a great aid in lessening the activities of the organism. In epidemic encephalitis a mild attack does not establish an immunity. On the contrary, it is not uncommon to obtain a history suggestive of encephalitis with improvement or even complete recovery, and some months or even a year later have the patient develop marked symptoms, definitely establishing the diagnosis. A case recently seen in consultation with Dr. W. A. Dennis, St. Paul, had a time interval of two months between the first manifestations and the final development of the disease. Another case, seen with Dr. L. S. Ylvisaker, St. Paul, had three definite exacerbations with marked improvement in the interval, during a period of six months. A third case, seen with Dr. E. B. Daugherty, of St. Paul, had an acute attack with diplopia, lethargy, temperature, bladder disturbance and delirium in February, 1920. This continued for six weeks to apparent recovery until June, 1923. Then he began to develop muscle rigidity and at present presents the typical Parkinsonian syndrome without tremor, not an infrequent sequel of epidemic encephalitis (an interval of over three years). A fairly large number of similar cases have been reported in the literature. These recurrences are probably not due to a re-infection but to a lighting up of the organisms present, similar to what occurs in syphilis.

Although epidemic encephalitis may develop at any age, the largest number of cases occurred between the ages of twenty-five and thirty-five. The oldest case in our series was sixty-nine years and the youngest case began five days after birth. This

little girl, seen in consultation with Dr. J. H. Libert, of St. Cloud, presented a most interesting picture. The family history was negative. The mother passed through a normal pregnancy and delivery. The child was well till the fifth day, when it had a convulsion, temperature 102 degrees, and became lethargic for ten days. It could be aroused for its feedings but readily lapsed into a stuporous state. About the twelfth day, it developed strabismus and gradually improved from the lethargy. Four weeks later it had a series of generalized convulsions with a moderate degree of temperature for five days. It gradually improved, developed physically but not mentally. It has never been able to walk or use its hands properly. At the time of my examination, the child was three years old. Her mentality was markedly impaired; she had a whining cry, but could not talk; certain noises, especially the ringing of the telephone, apparently terrified her; other, even loud, sounds did not seem to annoy her; she had internal strabismus; her upper extremities were awkward and markedly hypotonic; triceps, biceps and perist reflexes were normal. Her lower extremities were so hypotonic that her legs could be placed behind her neck without difficulty; her feet could be readily flexed so that the toes touched the anterior surface of the tibia; knee and Achilles jerks were absent; there was no Babinski. She propelled herself by rolling over and over sideways. At times, she seemed to take a little notice of bright objects.

As the mother was perfectly well during the entire pregnancy, gave no history of influenza or any other illness, one is at a loss to even surmise the source of the infection. The usual incubation period of encephalitis is given as ten days. Our youngster developed her first symptoms on the fifth day after birth.

Encephalitis complicating pregnancy is not infrequent. The mortality rate is surprisingly low and the effects on the newborn variable. Wechsler (investigation by the Association for Research in Nervous and Mental Diseases, page 11) reports 22 cases with four maternal deaths. In our series, one patient, seen in consultation with Dr. C. B. Teisberg, St. Paul, developed encephalitis at the fourth month of pregnancy, with marked myoclonic twitchings of the upper extremities, persistent tachycardia (120-140), profuse sweating, but gave normal birth to a healthy child at term. The termination of the pregnancy had no effect on the chronic manifesta-

tions in the mother. The child is developing normally in every way.

The literature so profusely covers the symptomatology with classifications, descriptions and case reports of this most protean disease, that it is needless to give more than a brief summary. Although multiple syndromes were observed during the entire period under discussion, more or less outstanding symptom groups occurred with each wave.

During 1919 and 1920, the predominant symptoms were: (1) pathologic drowsiness (lethargy); (2) cerebral nerve palsies—especially ophthalmoplegia; (3) acutely developing paralysis agitans syndrome (mask-like face; muscular rigidity); (4) pupillary changes; (5) bladder disturbances; (6) headaches.

In the early spring of 1921, when the third increase in the number of cases developed, the clinical picture changed somewhat and there was more evidence of meningeal irritation accompanied by profound toxemia. The outstanding syndrome was: (1) headaches; (2) neuralgic pain in extremities; (3) peculiar delirium; (4) profound toxemia; (5) cranial nerve palsies.

With the 1923 wave developing, entirely new clinical manifestations presented themselves. Lethargy, cranial nerve palsies and the Parkinsonian syndrome so frequent prior to this time were less common, but instead, two rather constant symptom groups were noted; in the one the myoclonic twitchings predominated; in the other, mental confusion with headache was characteristic. In the one the outstanding symptoms were: (1) history of acute nasopharyngeal infection with recovery; a week to ten days later (2) severe headaches, (3) neuralgic pains in the extremities, (4) myoclonic twitchings of the muscles of the face, extremities or trunk. In the other the predominating manifestations were: (1) headache; (2) insomnia; (3) mental symptoms especially at night (confusion; hallucinations; delirium); (4) bladder disturbances; (5) frequently no other evidence of organic nervous involvement or of pathologic reflex changes.

It is of interest to note that practically no change either in the localization or the character of the neuropathologic findings of the brain or cord was observed in these different symptom groups. The only exception noted was a more extensive involve-

ment in the region of the medulla in those cases associated with marked myoclonic twitchings.

In our series about 300 spinal fluid examinations were made. The outstanding feature was the disproportion between the marked clinical symptoms and the slight pathologic findings in the spinal fluid. Only one case gave a spinal fluid picture of marked intensity: the fluid was clear, under great and prolonged pressure, showed over one thousand lymphocytes, a marked globulin excess, a colloidal gold curve 0012234432, a web-like fibrin formation, a negative Wassermann; no bacteria in smear or by guinea-pig inoculation; no sugar estimate was done. In all the other fluids examined, the clinical manifestations were more pronounced than the spinal fluid findings indicated. The spinal fluid was normal throughout in 35 per cent of the cases. All spinal fluids except three were clear and colorless; one was bloody and two definitely xanthochromiac.

The case with the bloody spinal fluid was seen in consultation with Dr. A. Shimonek of St. Paul. A woman, aged 30, had a convulsion, developed headaches, diplopia, paresis and hyperesthesia of the right leg, a moderate degree of drowsiness and a temperature of 99-101 for one week, with a normal spinal fluid. Her systolic blood pressure was 140, diastolic 75. Within four weeks she had sufficiently improved to be up and around, when she suddenly became unconscious and died within 24 hours. A lumbar puncture at this time by Drs. A. Sweeney and G. N. Ruhberg gave a markedly bloody spinal fluid under pressure. No autopsy was permitted. Sclerotic changes with calcareous degeneration of the cerebral bloodvessels have been reported in chronic cases.* Although this has not been observed during the acute stage, the apoplectic onset and the bloody spinal fluid in this case were indicative of a cerebral hemorrhage occurring during the convalescent period.

One of the cases with the yellowish spinal fluid, seen in consultation with Dr. M. Larsen, St. Paul, was a male aged 45. His main symptoms were headache, photophobia, confusion and undue irritability, with a moderate degree of temperature. The spinal fluid was under pressure, markedly yellowish, and contained an excess of globulin, 12 cells, sugar 0.95. The spinal Wassermann and colloidal gold curve were negative. He made a satisfactory improvement in four months.

The other case, seen in consultation with Dr. F. A. Rieckhoff of Defiance, Ohio, was a woman, aged 26, with symptoms of headache, diplopia, photophobia, rigid neck and Kernig sign, marked delirium and profound toxemia; temperature between 99 and 103 degrees. Death occurred in twelve days. The spinal fluid was under moderate pressure, definitely yellowish, contained a globulin excess, 40 lymphocytes, a negative Wassermann, a colloidal gold curve 0000011221, sugar 0.1025. An examination made five days previous gave similar findings except that the cell count was over 200.

In the 65 per cent of the cases where the spinal fluid gave pathologic findings, two syndromes predominated. In the one we found increased pressure, a moderate pleocytosis 12-250 (mostly lymphocytes), a globulin increase, a luetic colloidal gold curve, and increase in sugar. In the other syndrome, the spinal fluid was under increased pressure, gave a cell-globulin dissociation, some change in the colloidal gold curve and sugar excess. An increase in pressure and a moderate excess of globulin were the two most frequent findings.

This brief study of some of the phases of epidemic encephalitis in Minnesota makes one apprehensive as to what the coming year may bring forth. Let us hope that the disease has reached its height. However, epidemics, as a rule, do not suddenly disappear, and in all probability many more cases with confusing and complex syndromes will make their appearance for some years to come.

THE RECTUM AS A FACTOR IN CHRONIC FOCAL INFECTION*

W. A. FANSLER, A.M., M.D.

Instructor in Surgery, University of Minnesota
Minneapolis

In recent years with the development of the roentgen ray and other laboratory methods the importance of focal infection has been very forcibly brought home to the medical profession. Its importance is admitted and the present problem is to discover every site in the body which may harbor such infection. Naturally those most accessible and easily examined were the first to be studied and reported upon. The teeth, the tonsils, the sinuses, gallbladder, appendix, prostate, the pelvic and other organs have all come in for their share of investigation. The result is that many affections which in the past would have had serious or fatal issue have been relieved or cured by eradication of exciting foci.

As a proctologist I wish to call attention to the rectum as a focus of infection and one which in the past has been frequently, I almost said usually, overlooked. I do not mean to say that every person with a systemic disturbance has a focus hidden in the rectum, but I do mean that in cases where a focal infection is suspected as the probable cause of the malady, in justice to the patient he cannot be dismissed until the rectum has been carefully examined as well as the other portions of the body which may harbor the exciting infection. The result of infection in the rectum upon the organism as a whole is the same as when located elsewhere in the body. These effects need not be discussed as they are well known and the literature is replete with articles on the subject of focal infection. It is the purpose of this paper to deal chiefly with the diagnosis of these infections in the rectum. With a little care and patience they are easily found.

The common types of infection either alone or in combination located in the rectum are as follows:

1. A general proctitis usually associated with colitis.
2. Infected hemorrhoids.
3. Ulceration of the rectum.

4. Cryptitis.

5. Sinuses leading off from the rectum.

In the cases of proctitis and colitis the diagnosis is usually very easily made by simple inspection through the proctoscope. For this reason further remarks are unnecessary other than to bear in mind that these conditions may be the cause of trouble elsewhere in the body and should not be neglected.

Infected hemorrhoids are usually not overlooked as they bleed and appear eroded. However, in some cases where they are large the site of infection may be hidden by the bulging of the hemorrhoid itself and the tumor must be pushed to one side before the ulceration is seen.

In cases of ulcer also there is usually little difficulty in diagnosis, a cursory inspection through the proctoscope being sufficient. However, occasionally there may be an ulcer of considerable size lying back of one of Huston's valves which may quite easily be overlooked. For this reason in examining one should be sure that *all* of the rectal wall has been inspected. While ordinarily we feel that an ulcer or wound which has free drainage does not cause much systemic disturbance, still this is not always the case as the following case will illustrate:

A male, thirty-eight years old, a mechanic by trade, complained that for about two weeks he had had some rectal discomfort and the passage of bloody mucus with the bowel movement. The past three or four days he had had pain in the right shoulder on motion and there was a slight swelling. When the proctoscope was passed nothing was seen except a little blood-tinged muco-purulent material clinging to the rectal wall. However, on more careful inspection a good sized ulceration was found on the upper side of the second valve of Huston. Under direct medication this ulcer quickly subsided and the pain in the shoulder also disappeared.

In case of cryptitis there is usually little constitutional effect although this condition is the most frequent cause of the sinuses which lead off from the rectum and which I will discuss later. The diagnosis of this condition is best made with a bivalve speculum. When opened this puts the lower part of the rectum on a stretch and thus spreads open the crypts, thoroughly exposing them for inspection. In connection with this it is well to remember that, while the crypt may appear healthy, at the lower end of the crypt is a blind pocket which may extend downwards underneath the anal mucous membrane as far as three-eighths of an inch. This acts as an admirable incubator for bacteria and is the most vulnerable site for the

*Presented before the annual session of the Minnesota State Medical Association, St. Paul, October, 1923.

development of infection. It also acts as a reservoir for products of infection from the crypts above and it is from this pocket, rather than from the upper part of the crypt, that the abscesses usually develop. It is therefore important that, even though the upper portion of the crypt appears normal, careful examination of its terminal portion be made.

It is the fifth or last type, namely, the sinus, which is the most often overlooked and to which I wish to call especial attention. Occasionally the openings of these sinuses are upon the wall of the rectum, above the area occupied by the crypts of Morgagni; but this is rare. Careful inspection of the rectal wall with the rectum distended with air and then exploring any suspicious areas with a probe will easily reveal them. In a great majority of cases, however, the sinus has an opening in the base of a crypt of Morgagni or more accurately speaking in the pocket at the lower end of the crypt of Morgagni. In this way the opening is well concealed and it must be carefully sought out. The sinus may extend directly into the tissues at right angles to the ano-rectal junction but in my experience this is rather rare. The more frequent type is that which extends outwards and downwards from the ano-rectal junction towards the external surface. Less often they extend upwards under the mucous membrane of the rectum. Another type described by Terrell, Landsmann and others is a sinus which extends downwards from these pockets just beneath the skin. These usually give no constitutional symptoms but are the cause of some of the cases of pruritis ani.

Regardless of the type of these sinuses their history of origin is the same, that is, they are always the result of an abscess formation. Aside from a few very rare injuries to the rectal wall by foreign bodies the general cause is about as follows: Due to some irritation, chemical or mechanical or infectious, the mucous membrane lining the crypts of Morgagni become inflamed, the pocket at the lower end acting as a reservoir, and this infection becomes chronic. Eventually due to sudden trauma of a large stool or diarrhea or the action of the infection itself this mucous membrane becomes broken and allows the infection to spread into the submucous tissues. If the infection is of sufficient virulence a frank abscess, which points externally and is readily recognized as the usual peri-rectal or ischio-rectal abscess, results. However, in many

cases this does not occur. The abscess forms rather slowly, surrounding itself with a firm thick wall of induration. The patient experiences some discomfort but there is frequently no visible external manifestations. If a bi-manual examination of the peri-anal and rectal structure be made at this time a distinct induration can be felt in the tissues. Pressure causes more or less pain. Before this spreads enough to give external signs the already diseased and weakened wall in the crypt gives way and the abscess is evacuated into the bowel. The pus is passed with the next stool and is usually unnoticed. The soreness which is present subsides and all noticeable symptoms disappear until the cycle repeats itself. Infrequently there is some tenderness in the glands of the groin, which may call attention to the fact that some infective process is present. The danger of these sinuses is that of any pus cavity where there is insufficient drainage.

The most simple method whereby these sinuses may be discovered during the period of quiescence is by dilating the lower end of the rectum, exposing the crypts of Morgagni and then exploring them with the tips of bent probes of various sizes. If sinuses are present the tip of the probe can be slipped into them although upon inspection they cannot be noted. During the intervals while the cavity is draining constitutional symptoms are usually too slight to be noticed by the patient. However, as soon as drainage is retarded the soreness returns, greater absorption occurs and there will frequently be a flare up of infection elsewhere as is always the case when an active focus of infection is present in the body.

While I have had a considerable series of these cases I will cite but two, which I think are typical of the effects of this condition. These cases were both seen during an acute exacerbation of their chronic trouble.

The first patient was a male who had had recurrent attacks of bronchitis. These attacks were very severe, usually confining the patient to bed for two or three weeks. They occurred in summer as well as winter and usually without any cause that could be determined. The attack which occurred previous to the one where I had the opportunity of seeing him had necessitated a three months' trip to the north woods to regain his health. He was underweight and his general appearance was that which is usually associated with a predisposition toward chest affections. During the bronchial attack in question he complained of some slight rectal discomfort and I had the opportunity of seeing him. By inserting the index finger into the rectum and palpating this area between the thumb and forefinger

a slight thickening could be palpated posteriorly but no definite mass could be felt. This area was slightly tender. Upon examination as indicated the tip of a probe could be easily slipped into a sinus opening into a crypt of Morgagni. This condition was operated and the patient has been well since and there has been no recurrence of the bronchial attacks. Upon questioning, the patient recalled that his previous bronchial attacks had been accompanied by slight rectal discomfort, but the bronchial symptoms had been so severe the slight rectal symptoms had been disregarded.

The second case was that of a man who had had recurrent attacks of lumbago for fourteen years. These would occur two or three times a year and last from two to six weeks, necessitating his remaining in bed. During these attacks he always had a feeling of fullness, heaviness and discomfort in the rectum and although repeated rectal examinations had been made nothing had ever been discovered. At the time I saw him he had just had an attack of lumbago. An induration the size of the kernel of an almond would be felt by bimanual examination and a sinus opening into a crypt demonstrated with a probe. There was no pus at the time of examination. The sinus, which had a very thick fibrous tissue wall, was dissected out and the man has been well since (over four years).

I have endeavored to be conservative in the presentation of this paper, for with the recent wholesale extraction of teeth it would seem that some conservatism in dealing with focal infection is necessary. I would not have the rectum enjoy the recent popularity of the teeth, but neither should it be entirely forgotten. We know that there are a definite number of patients having disturbances due to focal infection located in the rectum. This being true, in no case where focal infection is suspected or where the diagnosis is obscure has full justice been done the patient until a careful rectal examination has been made.

DISCUSSION

DR. L. A. BUIE, Rochester: I am very glad that Dr. Fansler has presented this paper on the subject of the rectum because it is so seldom that we ever hear one or read of it in a journal. Especially am I glad because he has presented the proctoscopic phase of the subject. A few minutes ago Dr. Corbett drew a tragic picture of a man with a spinal cord tumor—a man in a terrible state—and he claimed as one reason, the fact that this man had been unable to get a diagnosis because the diagnosis was difficult. I need not, I am sure, draw the familiar picture of a man coming in the last stages of carcinoma of the rectum—the emaciation, the symptoms of obstruction, and so forth. The condition of this man is not due to the fact that the examination or the diagnosis is difficult.

Thoroughness is the keynote to all diagnostic endeavor. The best internists are those who employ exhaustive methods of diagnosis. However, the attitude of even these men toward patients who present rectal complaints is astonishing. Few of us possess more of an equipment for rectal diagnosis than the index finger, and most of us who own proctoscopes have forgotten where they are stored.

Tragedy stalks into our hospitals and clinics every day; and our patient tells us that Doctor "So-and-So" has been treating him for bleeding piles. A diagnosis of cancer of the rectum is very frequently made at the time of hemorrhoidectomy in spite of the fact that it could much more easily have been done with a proctoscope. One of the chief reasons why this condition exists is the inefficiency of the teaching of proctology in undergraduate schools.

Dr. Fansler has presented a subject which will prove its worth. The conditions to which he refers cannot be diagnosed with the index finger. Proctoscopy is necessary. You must familiarize yourself with normal structures in the rectum and the anus, as well as these structures in disease, in order to be able to discover the things of which he has told you. Cryptitis and papillitis are just as much a disease entity as tonsillitis; and involvement of these structures causes the same amount of disturbance locally and systemically as foci. The removal of these conditions will produce cure in the same manner as tonsillectomy or any other surgical treatment of surgical conditions.

other surgical treatment of surgical conditions. There are few physicians who have not treated hemorrhoids with a cancer only three inches away. Let's be careful lest our antipathy for the rectum of our patient cause us to murder him.

WOOL GATHERING

Much newspaper notoriety is presently given to Lieutenant Wood, a young army officer stationed in the Philippine Islands. Rumor has it that he has profited heavily in stock manipulation. So important is this that even a congressional committee investigation is promised. Everybody is interested, and a possible epidemic of speculation of like manner is imminent. Before this epidemic gets under way, every physician, particularly, should be inoculated against it.

An old saying relates, "He who goes out to gather wool often returns himself well shorn." Doctors have long been the prize dupes in dissipating their earnings: most of them come into their numerous years of training without any business experience whatever to bring out any financial foresight that might at least be latent and forthcoming. Most of

them as students have been desperately "hard up." The first money they earn appears like "manna from heaven": the skies are clear; youth is to remain perpetual; time is no factor. So, the first precious years are either lost in garnering useless rubbish of stocks of all descriptions, or in struggling with unnecessary, unwise and injudicious obligations, entailing financial outlays that sorely postpone and interfere with the professional advancement known to be so necessary but daily becoming more impossible.

What would be the result if, when the association meets in St. Cloud next year, the President should ask in general assembly all those who "had gone wool gathering" to stand up? You know precious few would remain in their seats, particularly if the question was understood. And furthermore, if those who brought back any appreciable "wool" were asked to remain standing, the chairman would need no other fingers than his own to count them.

Regardless of all that may be said concerning our varied obligations—moral, civic or professional—we may as well face the bald facts: only five out of every one hundred people attaining the age of sixty-five are independent for their support. It should be evident that the first duty of every man is to make a living; his next is to provide for a family; then, to so live by spending less than he earns, to save, for his own period of possible dependency and that of his family. Saving is rarely a matter of income; it is far oftener the ability to spend less. Hence, saving is rarely impossible. Speculation and saving have as much in common as yachting and potato digging. The yachtsman may say that "sometime" he will dig potatoes, but the "house of 'sometime' is on the road to never." The lesson is perfectly obvious, but if any more were needed let a worthy medley of medical "wool gatherers" get together and agree to this equally obvious financial dictum:

"When we buy stock in somebody else's business, we bet on their ability to succeed. If we are right they rarely fail to find means to keep the profits. If they fail they can truly say, 'You would have gladly accepted the profits were they forthcoming. In the face of losses you miss only your money—we have lost all our time. Anyway you seem to

get it easily and you are amazingly lucky; we are most unhappy!"

No method of saving has so far been devised that can compare with proper life insurance. It is the first safeguard of the thoughtful young physician. Thereafter, any speculation that is presented should be passed upon by a conservative banker. The latter are just as numerous as reliable doctors. Make friends with them and listen to their counsel. They accept our word about their life and health. If we would take their advice on finance, in a few years we would save enough money to pay the Soldiers' Bonus!

E. L. T.

THE FRIENDS OF MEDICAL PROGRESS

There is a certain type of human being who is anti everything. We do not mean the individual, who whenever a statement is made can be counted upon to take the opposite stand and argue accordingly, but the one who never concurs in the judgment of the majority of those who have given the matter consideration. They are rather proud of being different from the ordinary run of men, and not being content to keep their opinions to themselves take great delight in winning others to their point of view. We see the type in many lines of activity. In national politics they are outstanding.

Then there is another type of mind that will not or more accurately cannot think for itself and blindly follows whoever takes the lead.

Both of these types make up the ranks of the anti-vaccinationists and anti-vivisectionists. The leaders of these organizations seem to be unable to reason logically, and misrepresentation has gained large numbers of recruits. Their strength is attested by the fact that within the last few years they have been able on three occasions (twice in California and once in Colorado) to submit for public vote an anti-vivisection bill so drastic that, if adopted, it would have closed every research laboratory and prevented the manufacture of vaccines and serums in the state. The health authorities, physicians and veterinarians would, it is true, have been simply inconvenienced in their fight against diseases such as smallpox, diphtheria, meningitis, typhoid and hog cholera by having to import fresh biological products from other states. It is anything but pleasant to contemplate the situation if such laws were to be enacted in every state in the

Union. And this is the actual danger if this element gets a foothold in one or two states.

On the cover of a widely circulated magazine, the official organ of an anti-vivisection organization in New York, appears the following:

"I invite all Anti-Vaccinationists, Anti-Vivisectionists, Eclectics, Homeopaths, Chiropraths, Osteopaths, Naturopaths of all branches, Christian Scientists, New Thoughtists, Theosophists, Medical Freedomists, and all brave and honest physicians of the Allopathic School (who secretly denounce the machinations and conduct of the political doctors) to send in their names and enroll as active participants in an Association of Free People against Medical Tyranny."

Let us hope that all this outlay of irregulars and "all brave and honest physicians" will not join the ranks.

To show how some of these organizations will deliberately falsify to gain their point, not long ago the Vivisection Investigation League, so-called, sent to a thousand newspapers the statement that Dr. W. J. Mayo demanded the protection of dogs from the vivisection table. Dr. Mayo, when questioned, made the statement, "The trouble with the anti-vivisectionists is that they are not only dishonest but willfully dishonest. The truth is not in these people."

In 1914 Mr. Rockefeller gave a million dollars to establish in New Jersey a laboratory for the study of animal diseases. The anti-vivisectionists persuaded the governor to veto a bill authorizing the work.

For years physicians could not get a whole-hearted laugh out of "Life." "Life" has found the anti-vivisectionists out and will have nothing more to do with them. Ernest Thompson Seton, the last scientific man in their ranks, resigned two years ago and told them why he did so.

Realizing the danger to the country of this anti-medical faction, a group of non-medical citizens organized in 1923 The Society of Friends of Medical Progress, whose avowed purpose is to aid all research and humane experimentation for the advancement of medical science, to inform the public of the truth concerning the value of scientific medicine to humanity and to animals, and to resist ignorant or fanatical persons or societies urging dangerous legislation. The name of Dr. Charles W.

Eliot, President Emeritus of Harvard, appears as honorary president. The honorary vice presidents include President Angell, of Yale, and the Honorable Charles Evans Hughes. The secretary is Mr. Edward Wigglesmith, Director of the Boston Museum of National History and headquarters are at 28 Newbury Street, Boston.

It is truly refreshing to hear of a move of this sort and we venture to predict that the society will have a large membership from the medical profession.*

*A check for one dollar payable to "Friends of Medical Progress, Inc." and sent to headquarters at 28 Newbury Street, Boston, will entitle the sender to associate membership.

MISCELLANEOUS

GAS BONDS—AND THE MISTAKE OF TRYING TO JUDGE AN INDUSTRY AND ITS SECURITIES BY A CASUAL GLANCE AT SURFACE INDICATIONS

By SAMUEL O. RICE

Educational Director, Investment Bankers Association of America

Time was when somebody made money by manufacturing bootjacks. Today there is no market for bootjacks and only a few, if any, are made. A bootjack factory would be an extremely poor basis for an investment. Bootjack making is virtually an obsolete industry.

Many persons have an erroneous notion that the industry of making manufactured gas is somewhat tending to decreased production because of electricity. They conclude that because electric lighting has caused a great decrease in the use of gas for lighting homes and streets that the market for gas has been reduced. That notion comes as near being an absolute error as any notion could be. In the last 10 years production of manufactured gas in the United States has increased 100 per cent. In the same period consumption of gas for industrial purposes increased 1,000 per cent in the United States.

The manufactured gas business was scarcely ever more prosperous than now. The reason is because of the increased use of gas in industry. Modern heating processes in manufacturing use great quantities of gas, for gas has been found to be the most economical and efficient in heat treating processes of manufacturing.

Of course, the casual observer may not be blamed for erroneously concluding that electric lighting has cut in on the gas business. It looks that way on the surface perhaps, but that simply shows how dangerous are surface indications. The fact is that electricity really did the gas industry a service when it took the little home-lighting load off the gas companies and enabled the gas companies to use their capital and energies for developing the larger industrial

field. Electricity is cheap for power, but expensive for heating purposes. Gas is cheap for heating purposes.

Gas also has the advantage of diversified use. In periods of depression people do not stop using gas stoves. In the future development in the use of gas, men of long experience in public utilities confidently predict that gas will be increasingly used for heating in cities. Transportation of gas is much cheaper than transportation of coal. Not only are rail and water transportation of coal expensive, but local hauling of coal is becoming an expensive proposition in many cities. The indications all point to an increased use of gas for heating homes and business buildings in the large cities.

The foregoing is, of course, openly conjectural. It is, however, sound. The future of the gas business seems assured. Certainly its present situation is gratifying. I am led to write this because I have heard a number of surface-indication logicians object to gas bonds because electricity had almost usurped gas lighting in homes. One such person even advised a widow to sell certain fine gas company bonds her husband had left her. It was abominable advice, based on ignorance. The bonds in question were safe, high-yielding, very desirable.

Perhaps I may be a bit tiresome in repeatedly pointing out that an investor should go to some honest, dependable authority to learn the true worth of any investment he is considering. What sort of an investigation can any man make of an enterprise in which he contemplates investing? He can, if he has time, visit the factory, the electric plant, the gas plant or other enterprise whose bonds he is considering. He can look at them carefully, go over the books, and then what does he know? How can he possibly be competent to judge whether it is a good efficient plant, whether its different units are all right, whether as a whole it can produce and meet competition sufficiently well to pay interest or dividends? How can he know that the "corporate structure" is right? By that I mean how can he determine accurately that it has been financed most efficiently, that the right proportion of common stock, or of preferred stock, and of bonds has been judged? No man unless he is an investment banker can do that and usually investment bankers have engineers, accountants, attorneys and all sorts of specialists to help them do it.

In these articles I have determinedly endeavored not to try to persuade any one to buy any particular issue of any investment security. Instead, I have tried to show how complex a business is the making of sound investment securities. In my own little investments I never buy anything without talking it over with one or more investment bankers. I suppose I am in as good a position as any one could be to garner "inside tips," but strange as it may seem I have found the much-talked-of "inside tip" virtually non-existent. I have found, however, a world of sound, dependable information, frankly and openly given. As a result, if I may be pardoned a further personal allusion, I have never lost a penny in investments, either my own small funds or money of two estates I have administered. It all depends on the investment dealer you select. I know several hundred honest and competent ones—surely any physician is good enough judge of character to select one and not put his money into schemes of crooked or incompetent promoters.

OBITUARY

DR. JAMES A. QUINN

Dr. James A. Quinn died at St. Paul, December 27, 1923. Dr. Quinn was born near Springfield, Ill., December 8, 1855, and, with his parents, William B. Quinn and Louisa Tomilin Quinn, settled the same year upon a farm at the present site of Merriam Park in St. Paul, where he lived until he was eleven years of age. The present Quinn Farm, now bounded by Snelling, Larpenetour and Hamline Avenues, near the State Fair Grounds, has been his home since 1866.

Dr. Quinn, as a boy, attended the public district schools, and at an early age was sent to a Methodist Seminary in Illinois, in preparation for the ministry. Upon returning to Minnesota, he attended the State University, finishing there in 1876. He graduated in medicine at Columbia, in New York, in 1880, and, soon after completing his internship in New York hospitals, became associated with Dr. J. H. Murphy, one of the pioneer surgeons of St. Paul. He was coroner of Ramsey county four terms of two years each, the last two terms being indorsed by all political parties. Dr. Quinn was president of the Ramsey County Medical Society in 1898. He was chief surgeon of the Great Northern Railway from 1892 to the time of his retirement from practice, two years ago, on account of ill health.

In the passing of Dr. Quinn, one of St. Paul's most widely known, popular and picturesque characters in the profession is gone from us. As a farmer boy, with rod and gun, roving the present sites of St. Anthony Hill and the Midway district, from Fort Snelling to St. Anthony (now Minneapolis), and, later, as a young practicing physician he was known by every old-timer in this section, and his genial, cordial and companionable disposition rolled up probably the largest acquaintance ever enjoyed by any physician in St. Paul; among the profession of the state, too, and the entire Northwest, in years gone by, no society or association meeting seemed complete without him.

The "call of the wild" was strong within him and his hunting season, each year, meant from the first day of chicken season to the last day of the big game season. Up to the advent of the automobile, Dr. Quinn was a most familiar picture on the streets, driving his buckskin mare, "Topsy," who was as well known as he. In his capacity as surgeon for many railroads running in and out of St. Paul, his acquaintanceship reached far and wide and every village along two, at least, transcontinental lines in Minnesota, the Dakotas and Montana held one or more persons who knew him.

Careless and indifferent as to the obligations of others to him, he was most punctual and exact in his sense of obligation to others; and his devotion to his professional brethren never lagged. No road was too long nor weather too bad to keep him from the assistance of the young man in the profession who called for his help and his cheery, optimistic and encouraging words will be remembered long and well.

DR. D. EDMUND SMITH

Dr. D. Edmund Smith was born at Winona, Minnesota, December 20, 1867, the only son of Charles Henry Smith, of Potsdam, New York, and Clarissa Maria Moody (Smith), of Canton, New York. There were two sisters, Ruth Smith (See) and Mary Moody (Curran).

His father was a manufacturer, who moved from New York to Minnesota, and from Minnesota to Illinois, where Dr. Smith obtained his early training. He completed the high school in Chicago and then attended Amherst College, graduating with a B.A. He took his medical degree in 1894 at Rush, going to Johns Hopkins for post-graduate work about 10 years later.

In 1894 he came to Minneapolis as an intern in the old Asbury Hospital and had remained here in active general practice until his death, Dec. 15, 1923. In 1896 he married Alice Clark Dyer, who died in 1919. One daughter, Esther, survives her parents.

He served at various times on the medical staff of General Hospital, St. Barnabas and Asbury; was an active member of Westminster Presbyterian Church; belonged to the Chi Psi (academic) and Nu Sigma Nu (medical) fraternities; the Six o'Clock Club, and the Alliance Francaise. He was a member of the American Medical Association and Hennepin County Medical Society. He taught for a time at the University of Minnesota Medical School, about 1898.

Early in 1918 Dr. Smith entered the service of the American Red Cross with a commission of captain. In April, 1918, he was sent to France and stationed at Lourdes in the Pyrenees near the Spanish border. Here he found an opportunity for unique and extremely humane service. Being the only American doctor in the area, he established an American Maternity Hospital of sixty beds in which he performed a great and worthy service. He also attended the refugee men, women and children of the five other hospitals of Lourdes, which had been taken over with all the hotels, by the French Red Cross. At times he was the only physician in charge of all these homeless and starved people, whose numbers ran to five or six thousand. Insufficient help, insufficient food, and lack of medical supplies made this service a terrible one.

Dr. Smith remained at this post until the end of the war and gave such unselfish and untiring attention to it as to permanently impair his own health. In recognition of his devotion to his duty during this period, he received from France the Order of the Reconnaissance Francaise, and from Belgium the Order of the Angel of Rheims.

The death of his wife and his own depleted physical condition after his arduous service overseas resulted in his death, from a complication of diseases, December 15, 1923. The society is proud to have numbered him in its membership.

GEORGE WILLIAM KIRMSE

Dr. George W. Kirmse was born February 26, 1883, at Dubuque, Iowa, the son of Cora Ritter Kirmse and William D. Kirmse.

His early life and education through high school was at Dubuque. He obtained his medical education at the University of Chicago and St. Louis University Medical School,

graduating from the latter in 1907. After ten years of general practice at Clayton, Mo.; at St. Louis, Mo.; Smith Center, Kansas; and Frazee, Minnesota, he took up the special line of eye, ear, nose and throat. His practice at Frazee, Minnesota, was as a partner of Dr. Edgar R. Barton, who became a member of the Hennepin County Society in 1919.

Dr. Kirmse prepared himself for special work by post-graduate courses of study at St. Louis University, New York Eye and Ear Infirmary, and Manhattan Eye, Ear, Nose and Throat Hospital. He came to Minneapolis and became associated with Dr. George A. Kohler, with whom he practiced until his death.

During the World War he volunteered in the United States Navy and was commissioned a lieutenant in the Medical Corps. He maintained this connection after the war and was a member of the Naval Reserve at the time of his death.

He belonged to the Episcopal Church, the Elks, the Automobile Club, the Y. M. C. A., and the Masonic Fraternity. His medical affiliations were the Hennepin County Medical Society, the Minnesota State and American Medical Associations.

Dr. Kirmse is survived by his wife, Aldine Jacobsmeyer (Kirmse) and their two sons; by his parents and two sisters—Lillian Kirmse Christy, of Dallas, Texas, and Cora Kirmse Preitaner, of Dubuque, Iowa.

Dr. Kirmse was a great lover of outdoor recreation and especially hunting. It was on a hunting expedition that he met his untimely death, being drowned in Lake Sylvia, near South Haven, Minnesota, November 25, 1923. The exact manner of his death is unknown. With a cousin he was last seen in a boat on the lake during a storm. Both bodies were recovered after much search, several days after their empty boat was washed ashore.

JOHN MICHAEL EGAN

Dr. John M. Egan was born at Osseo, Minnesota, January 5, 1883, the son of Mary Jane Ryan Egan and Edward Egan.

His father was a New York man who moved west to become a rancher. Dr. Egan obtained his early education at the village school and his high school degree at Anoka. He obtained his medical degree in 1907 at the University of Minnesota. There followed a year's internship at the Minneapolis City Hospital.

From 1908 to his death he practiced continuously in Minneapolis. In 1912 he formed a partnership with Dr. W. J. Byrnes, which relationship was permanent. Dr. Egan was a general practitioner on the staff of St. Mary's Hospital, and a very active and hard-working man.

He belonged to the Catholic Church and was a member of the Knights of Columbus, the Ancient Order of Hibernians, the Benevolent and Protective Order of Elks, the Phi Beta Pi Fraternity, the Automobile Club, and the Golden Valley Golf Club. He was a member of the Hennepin County Medical Society, the Minnesota State Medical Association and the American Medical Association.

He is survived by a wife and four children.

He died suddenly, at his home, from acute dilatation of the heart, on November 30, 1923.

DR. WARREN A. DENNIS

The Administrative Board of the Medical School of the University of Minnesota records with great regret the death of Dr. Warren Dennis, Associate Professor of Surgery.

Dr. Dennis died in the prime of life and in the full activity of his calling. Intellectually mature, with an orderly mind developed by constant study and broad experience, he had attained to a high place in the profession.

By those of us who knew him best, he will be remembered as much for his personal charm and his sterling worth as for his high professional attainments.

The story of his life is one of unassisted effort. Losing both father and mother at an early age, he was cared for by relatives, to whom, during all the succeeding years, he has made every remembrance. His years of study and graduation at the University of Wisconsin were achieved, in the main, through his own initiative. The work he did there is suggested by the fact that he stood high in Phi Beta Kappa. Two or three years of school teaching furnished sufficient support to permit him to enter the Medical School of the University of Minnesota in the fall of 1893, from whence he graduated in 1896.

With an intense desire for knowledge, trained in study, experienced in the expression of his thoughts, relatively older in judgment than his fellows, more fully appreciative of the curriculum, acknowledging the efforts of his teachers, stimulating them, by his earnest endeavor, his interest and his helpfulness in the affairs of others he immediately obtained and held a high position of esteem and respect not only among his classmates, but among the faculty and in the profession, with whom he came in contact in future years.

He interested himself in medical affairs and wherever he went he won recognition. He was a past president of the Ramsey County Society and of the Minnesota Academy of Medicine, a District Councilor of the Minnesota State Medical Society and Secretary of the Western Surgical Society.

He held commanding positions during the two recent wars; as major surgeon of the 15th Minnesota in the Spanish-American War, and as major surgeon and lieutenant colonel of the 88th Base Hospital, with which he served in France during the World War.

Never physically robust, his lack of resistance was well known to his friends and associates. His interest in his work led him many times to physical exhaustion. It was this tendency doubtless that determined the too early end of his career.

His relaxation was largely along lines of study, particularly in the languages, developing a ready command of German, French, Spanish and Italian. To the abilities that made him a splendid surgeon were added the judicial qualities of mind, which marked him as not only a wise adviser but a true counsellor and friend.

The Medical School offers to his widow and children its sympathy and the assurance of its appreciation of the rich legacy of love and appreciation he has left to them and to his friends.

DR. JOHN HUNTER ADAIR

Dr. John Hunter Adair, a practicing physician in Owatonna since 1884, died at his home Sunday morning, January 6, at the age of 65 years.

Dr. Adair was born on the Adair farm homestead in Havana, Steele County, July 26, 1858, the son of two of the county's first settlers, Robert and Flora Adair. His early education was received in the district school near Havana station and at Pillsbury Academy. From 1879 to 1880 he attended Carleton College, then going to Chicago to study medicine at Rush Medical College, from which he was graduated in 1883.

For one year following his graduation, Dr. Adair practiced medicine in Winnebago, after which he returned to his home city, Owatonna, where he practiced up to the time of his death. Dr. Adair had been an active member in his county and state medical societies, being president of the Minnesota State Medical Association in 1920. He was also an active member of the Southern Minnesota Medical Association, being a founder of the original society. In October, 1917, Dr. Adair was elected a fellow of the American College of Surgeons. In addition to his work as a general practitioner, he had been physician of the State Public School at Owatonna for 34 consecutive years.

Dr. Adair was active in civic affairs, being a prominent member of the Owatonna Rotary club. He was also a member of the Presbyterian church, the Knights of Pythias lodge, and the Ancient Order of United Workmen.

Dr. Adair's decline in health dated from the time of his wife's death in January, 1917. His great efforts in opposing the influenza epidemic in 1918-1919 were also contributory factors. His final illness, however, was of only a week's duration, resulting in a sudden demise, which was a shock to the community in which he lived as well as to all those who knew him.

He is survived by two daughters, Mrs. F. R. Kerman, of Berkeley, California, and Miss Catherine Adair, of Owatonna, and a sister, Miss Esther Adair, of Owatonna.

WILLIAM WHITFORD

William Whitford passed away December 10, 1923, twelve hours after his return from reporting the thirty-third annual meeting of the Western Surgical Association at Colorado Springs. At the time of his death he was the official stenographer for thirty medical societies throughout the United States. He had been the Official Stenographer of the American Medical Association and the Southern Surgical Association for thirty-four consecutive years.

He was born in Cornwall, England, in 1858. He was an honorary member of the Southern Surgical Association and Tennessee State Medical Association, a member of the Standardization Committee of the National Shorthand Reporters Association and at one time served as its President.

Mr. Whitford is well known to the medical profession of Minnesota, having been the official stenographer of the State Medical Association for several years.

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

AMERICAN CONGRESS ON INTERNAL MEDICINE

The Eighth Annual Clinical Session of The American Congress on Internal Medicine will be held in the amphitheatres, wards and laboratories of the various institutions concerned with medical teachings, at St. Louis, Mo., beginning Monday, February 18, 1924.

Practitioners and laboratory workers interested in the progress of scientific, clinical and research medicine are invited to take advantage of the opportunities afforded by this session.

Address inquiries to the secretary-general, Dr. Frank Smithies, 1002 N. Dearborn St., Chicago, Ill.

CLAY-BECKER COUNTY MEDICAL SOCIETY

Dr. G. G. Haight, of Audubon, was elected president of the Clay-Becker Medical Society at the annual meeting of the society held in Moorhead December 27, 1923.

Dr. Martin Gergheim, of Hawley, was elected vice president; Dr. J. H. Heimark, of Moorhead, secretary and treasurer; Dr. W. H. Aborn, of Hawley, delegate to the Minnesota State Medical Association. The next meeting of the society will be held in March.

A dinner at the hotel was served preceding the meeting at which addresses were given by Dr. B. K. Kilbourne, of Fargo, who spoke on "Vital Statistics and Contagious Diseases," and Dr. L. J. Evans, connected with the Fargo Child Health Demonstration. A general discussion followed the meeting.

CENTRAL MINNESOTA MEDICAL ASSOCIATION

Dr. W. Robertson, of Litchfield, was elected president of the Central Minnesota Medical Association at the annual meeting held in Willmar December 27, 1923. Other officers elected for the coming year were: Vice president, Dr. L. W. Anderson, Atwater; secretary-treasurer, Dr. C. L. Scofield, Benson.

"Tonsillectomy Under Local Anesthetic," was the subject of a paper read by Dr. Will Robertson, Litchfield. Dr. E. H. Frost, Willmar, presented a paper on "Criticisms of the Medical Profession," which was followed by a talk on "Minnesota's Standing in Disease Prevention," given by Dr. C. L. Scofield, Benson. The president's address was delivered by Dr. John C. Jacobs, of Willmar.

FREEBORN COUNTY MEDICAL SOCIETY

Officers of the Freeborn County Medical Society for the coming year were elected at the annual meeting held in Albert Lea, December 17, 1923, as follows: President, Dr. J. P. von Berg, Albert Lea; vice president, Dr. W. L. Palmer, Albert Lea; treasurer, Dr. J. R. Nannestad, Albert Lea; secretary, Dr. F. G. Folken, Albert Lea. The following were elected to the Board of Censors: Dr. H. D. Burns, Albert Lea; Dr. J. R. Freeman, Glenville; Dr. C. R. Buttruff, Freeborn; and Dr. F. W. Calhoun, Albert Lea.

MAYO CLINIC LECTURES

Visiting physicians are invited to the Mayo Foundation lectures which are held Monday, Thursday and Friday evenings of each week during the winter and also to the staff meetings each Wednesday evening.

The program of lectures for February and March is as follows:

- Feb. 1—Cancer and Allied Subjects—Dr. A. C. Broders.
- Feb. 4—Uterine Prolapse—Dr. J. C. Masson.
- Feb. 7—Radium in the Treatment of Gynecological Cases—Dr. L. J. Stacy.
- Feb. 8—Dysmenorrhea—Dr. L. J. Stacy.
- Feb. 11—The Therapeutic Application of the Rays of Radium—Dr. H. H. Bowing.
- Feb. 14—Diseases of the Esophagus—Dr. P. P. Vinson.
- Feb. 15—Endoscopic Removal of Foreign Bodies from the Food and Air Passages—Dr. P. P. Vinson.
- Feb. 18—Significant Signs and Physiological Considerations in the Diagnosis of Empyema—Dr. W. S. Lemon.
- Feb. 21—End Results of Non-Tuberculous Inflammatory Disease in the Lung—Dr. W. S. Lemon.
- Feb. 22—Differential Diagnosis of Mediastinal Tumors—Dr. F. W. Gaarde.
- Feb. 25—A Review of the Present Status of the Treatment of Asthma—Dr. F. W. Gaarde.
- Feb. 28—The Treatment of Empyema—Dr. C. A. Hedblom.
- Feb. 29—The Treatment of Pulmonary Suppuration with Special Reference to Bronchiectasis—Dr. C. A. Hedblom.
- Mar. 3—The Treatment of Tumors Involving the Bony Chest Wall—Dr. C. A. Hedblom.
- Mar. 6—Nephritis—Dr. N. M. Keith.
- Mar. 7—Nephritis—Dr. N. M. Keith.
- Mar. 10—Diabetes—Dr. R. M. Wilder.
- Mar. 13—Diabetes—Dr. R. M. Wilder.
- Mar. 14—Vascular Diseases—Dr. G. E. Brown.
- Mar. 17—Diseases of the Joints—Dr. G. E. Brown.
- Mar. 20—Diseases of the Adrenals—Dr. L. G. Rowntree.
- Mar. 21—Diseases of the Pituitary—Dr. L. G. Rowntree.
- Mar. 24—Diseases of the Rectum and Anus—Dr. L. A. Buie.
- Mar. 27—Diseases of the Rectum and Anus—Dr. L. A. Buie.
- Mar. 28—Chronic Conditions of the Colon—Dr. A. H. Logan.
- Mar. 31—Diseases Due to Intestinal Parasites—Dr. L. W. Pollock.

WINONA COUNTY MEDICAL SOCIETY

The annual meeting of the Winona County Medical Society was held at the Winona General Hospital, January 8, 1924. Officers elected for the ensuing year included the following: President, Dr. Samuel Schaefer, Winona; vice president, Dr. W. W. Nauth, Winona; treasurer, Dr. F. T. Benoit, Winona; secretary, Dr. C. P. Robbins, Winona. Dr. W. F. C. Heise was elected to act as delegate to the next annual meeting of the State Medical Association with Dr. Irving W. Steiner as alternate.

The paper of the evening was given by Dr. S. W. Adler, who spoke on "Handling Contagious Diseases of Childhood." The next meeting of the society will be held in April.

THE MINNEAPOLIS SURGICAL SOCIETY

The regular monthly meeting of the Minneapolis Surgical Society will be held Thursday, February 7, 1924, at the University Hospital from 9 to 12 A. M. Operative clinics will be held by Dr. A. C. Strachauer, Dr. A. A. Law, Dr.

Johnson and Dr. Cameron, to be followed by a pathological conference with Dr. E. T. Bell and staff.

A dinner will be served at the University Hospital at 6:30 P. M. followed by the presentation of cases, and a paper by Dr. R. E. Farr on "Local Anesthesia of the Abdominal Sympathetic System."

NICOLLET-LE SUEUR COUNTY MEDICAL SOCIETY

The annual meeting of the Nicollet-Le Sueur County Medical Society was held at Le Sueur, December 13, 1923. Dr. F. W. Behmler, of Lafayette, was re-elected president of the society, and Dr. J. E. Le Clerc, of Le Sueur, was re-elected secretary.

The subject of the president's address was "The County Society." Other papers read included "The Blood in Health and Disease," by Dr. W. W. Covell, of St. Peter, and "Cancer," by Dr. F. A. Dodge, Le Sueur.

SCOTT-CARVER COUNTY MEDICAL SOCIETY

At the annual meeting of the Scott-Carver County Medical Society held at Jordan, December 6, 1923, the following officers were elected for the coming year: President, Dr. F. J. von Bohland, Belle Plaine; vice president, Dr. F. H. Buck, Shakopee; secretary-treasurer, Dr. H. W. Reiter, Shakopee. Dr. H. W. Reiter and Dr. John Landenberger, New Prague, were elected as delegate and alternate to the next annual meeting of the State Association.

STEELE COUNTY MEDICAL SOCIETY

Dr. Jerome F. Smersh, of Owatonna, was re-elected president of the Steele County Medical Society at the annual meeting held in Owatonna, December 11, 1923. Other officers elected were: Vice president, Dr. B. Melby, Blooming Prairie; secretary, Dr. A. B. Hart, Owatonna; treasurer, Dr. F. M. Smersh, Owatonna.

The annual dinner at the Hotel Owatonna opened the session followed by the election of officers. Dr. Charles S. McVicar, of Rochester, then delivered an address on "The Diagnosis of Dyspepsia," which was followed by a general discussion.

WATONWAN COUNTY MEDICAL SOCIETY

Dr. F. L. Bregel, of St. James, was elected president of the Watonwan County Medical Society at the annual meeting held in Madelia in December. Other officers elected are: Vice president, Dr. O. E. Hagen, Butterfield; secretary-treasurer, Dr. H. B. Grimes, Madelia. Dr. O. H. Ternstrom, of St. James, was elected to act as delegate to the annual meeting of the State Medical Association in October.

OF GENERAL INTEREST

Dr. and Mrs. Geo. E. Putney, of Paynesville, are spending the winter in Kansas City.

Dr. and Mrs. G. J. Ferreira, of Aurora, are the parents of a son, born December 24, 1923.

A son, Henry Walter, was born to Dr. and Mrs. J. deJ. Pemberton, Rochester, January 6.

A daughter was born to Dr. and Mrs. Harold T. Nesbit, of Rochester, Saturday, December 29.

Dr. B. V. Bates, formerly associated with Dr. C. F. Ewing, at Wheaton, is now located at Browns Valley.

Dr. William Crandall has disposed of his practice at Browns Valley and is now located at Graceville.

Charles Wesley, Jr., is the name of the son born to Dr. and Mrs. C. W. Barrier, Rochester, December 10, 1923.

Dr. A. J. Gibson, following a trip to Europe, Egypt, and South Africa, has returned to Duluth for the practice of medicine.

Dr. W. O. Ott, formerly assistant to Dr. A. W. Adson, Rochester, is now associated with the Harris Sanitarium, of Fort Worth, Texas.

Dr. L. M. Randall, formerly of Iowa City, Iowa, is now associated in the practice of medicine with Dr. R. D. Mussey, Rochester.

Dr. and Mrs. H. R. Hartman, of Rochester, have gone south for several months of travel through the Central American countries.

Dr. John Lyons, formerly of the Mayo Clinic, Rochester, is now located in Washington, D. C., where he will continue the practice of medicine.

Dr. O. J. Hagen, who recently completed a four months' course of study in eastern clinics and hospitals, has returned to his practice at Moorhead.

Dr. Harold N. Nagel, who recently completed his internship at the Minneapolis General Hospital, is now located at Waconia for the practice of his profession.

Dr. H. O. Altnow, of Mandan, N. D., is now in Cambridge, Mass., where he will enter the Harvard Medical College for a post-graduate course in children's diseases.

Dr. Chester Oppegaard, who recently completed his medical course at the University of Minnesota, is to be associated with his brother, Dr. M. O. Oppegaard, at Crookston.

Dr. K. V. Overend has resumed the practice of medicine at Hallock following a year's study in Germany and Austria, where he took advanced work in diseases of the ear, nose and throat.

Announcement has been received of the marriage of Dr. James B. Vail, of New York Mills, to Miss Verly Wheadon, of Balaton, which took place at the home of the bride's parents, January 1.

Dr. and Mrs. G. L. Jacquot, of Tyler, are spending the winter on the west coast, where Dr. Jacquot is pursuing a

special course of study in the medical department of Berkeley Institute near Los Angeles, Cal.

Dr. Bernard H. Simons, of Chaska, and Miss Adelaide Collins, of Minneapolis, were united in marriage in Minneapolis, December 27, 1923. Following a wedding trip in the East, Dr. and Mrs. Simons are now at home in Chaska.

Dr. W. W. Holley, formerly of Warren, is now located in Los Angeles, California. Dr. Holley will be succeeded as a member of the Warren Hospital staff by Dr. M. George Milan, formerly superintendent of the Oakland Park Sanatorium, Thief River Falls.

Dr. George D. Rice, of St. Cloud, a former major in the American army medical corps in France, was named medical officer in charge of the tenth district veterans' hospital being erected in St. Cloud, according to a telegram received by Dr. Rice from Washington, January 8.

Dr. A. G. Beyer, who after completing a post-graduate course in diseases of the eye, ear, nose and throat in Vienna, resumed his former practice at Red Wing, has accepted a position as member of the Dr. Wm. Mithoefer eye, ear, nose and throat clinic of Cincinnati, Ohio, where he is now located.

Dr. C. E. Anderson, who recently completed a year's work at the Swedish Hospital, Minneapolis, has taken over the practice of Dr. E. A. D. Jones, at Garretson, S. D. Dr. Jones plans to take a post-graduate course extending over a period of eighteen months in the eastern hospitals and colleges.

Dr. Bruce W. Jarvis, and family, of Minneapolis, sailed December 11, on the S. S. Korea Maru from San Francisco for Hong Kong, en route to China to become a member of the medical missionary staff of the North China Conference of the Methodist Episcopal church. He will be stationed at Taianfu in the Province of Shantung. Within a radius of fifty miles the territory around Taianfu has no missionary hospital or dispensary, and only one Chinese physician of western training. It is estimated that the medical center which Dr. Jarvis is to establish must serve a population of 4,500,000.

During the past year seven State Boards of Medical Examiners have perfected arrangements for the acceptance of the certificate of the National Board, in lieu of their own examination of candidates for licensure. The states are as follows: Illinois, Maine, Massachusetts, New York, South Carolina, Tennessee and Texas. The states accepting the National Board's certificate now total twenty eight and are as follows: Alabama, Arizona, Colorado, Connecticut, Delaware, Georgia, Idaho, Illinois, Iowa, Kentucky, Maine, Maryland, Massachusetts, Minnesota, Nebraska, New Hampshire, New Jersey, New York, North Carolina, North Dakota, Pennsylvania, Rhode Island, South Carolina, Tennessee, Texas, Vermont, Virginia and Washington.

A Convalescent Home for Women, located at 577 Oakland Avenue, St. Paul, Minn., has been opened by the Junior League of St. Paul to take care of patients recovering from any illness other than mental, contagious or infectious diseases. The home will accommodate fourteen women and is open to patients recommended by a doctor, who will

remain in attendance or be called when necessary. The home, when filled to capacity, will be only half self-supporting, the deficit of several thousand dollars each year to be guaranteed by the Junior League of St. Paul. The Junior League of St. Paul, Inc., is a branch of the National organization of Junior Leagues of America, Inc., formed to provide volunteers and financial support for social, economic, and philanthropic work. On the advisory board of the Convalescent Home are: Mrs. Joseph Stronge, Mrs. Wm. Mitchell, Mr. Charles Bunn, Dr. Jeannette McLaren, Dr. John L. Rothrock, Dr. John Rogers, Dr. Robert Earl, Dr. John Abbott, Dr. C. N. McCloud, Dr. Wm. C. Carroll and Dr. E. G. Sterner

Announcement has been received of the annual award of the Sofie A. Nordhoff-Jung Cancer Research prize, which was awarded for the first time in December, 1923, the recipient being Dr. Johannes Fibiger, professor ordinarius in pathological anatomy at the University of Copenhagen. Dr. Fibiger won the prize for his demonstration, following repeated experimentation, that parasites play an important role in the formation of certain types of tumors in the proventriculi of rats. Where others had failed after years of persistent researches, Dr. Fibiger first met with success in artificially inducing malignant tumors through external irritations and so threw wide new avenues to future findings. Fibiger and his associates have contributed generously to the literature of cancer production through the feeding to rats of oats and the application of tar to their issues. The award was made as a recognition of the most conspicuous work in the world literature bearing on cancer research, the commission on the award being composed of Professors Borst, Doederlein, v. Romberg and Sauerbach, all of the University of Munich.

NEW AND NON-OFFICIAL REMEDIES

The following articles have been accepted by the Council on Pharmacy and Chemistry:

CUTTER LABORATORY:

Anti-Anthrax Serum for Human Use-Cutter.
Diphtheria Toxin-Antitoxin Mixture-Cutter.
Diphtheria Toxin for the Schick Test-Cutter.
Rabies Vaccine-Pasteur (Cutter).
Tetanus Antitoxin for Human Use (Concentrated)-Cutter.

E. R. SQUIBB & SONS:

Diphtheria Toxin-Antitoxin, 0.1 L+.

WINTHROP CHEMICAL COMPANY:

Elixir of Veronal.

NEW AND NON-OFFICIAL REMEDIES

National Radium Emanator.—A portable appliance for activating water with emanation; the emanation is emitted from a solution of radium chloride, barium chloride and sodium chloride. The appliance is claimed to produce 40 microcuries (150,000 Mache units) of radium emanation to 1,000 c.c. of water daily. The actions, uses and dosage of radium are discussed in New and Non-official Remedies,

1923, p. 255. National Radium Products Co., New York. (Jour. A. M. A., December 8, 1923, p. 1953.)

Iodostarine-Roche—Diiodotariric Acid.—An iodine addition product of tariric acid, derived from the fruit of a species of *Picramnia*. Iodostarine-Roche contains 47.5 per cent of iodine. It acts in the tissues similarly to inorganic iodides. It is not broken up in the stomach, but a portion of the iodine is split off when it enters the intestine. The undecomposed portion is readily absorbed and, as in the case of other fats, is largely deposited in the tissues where it is slowly split up. The action of iodostarine-Roche is exerted more slowly than that of the inorganic iodides. Iodostarine-Roche is supplied in the form of tablets iodostarine-Roche 0.25 gm., and as chocolate tablets iodostarine-Roche containing iodostarine-Roche equivalent to iodine 0.01 gm. Hoffmann-LaRoche Chemical Works, New York. (Jour. A. M. A., December 15, 1923, p. 2032.)

Tetanus Antitoxin for Human Use-Cutter.—Tetanus antitoxin, concentrated (see New and Non-official Remedies, 1923, p. 284), marketed in syringes containing 1,500 and 5,000 units each. Cutter Laboratory, Berkeley, Calif.

Diphtheria Toxin-Antitoxin Mixture-Cutter.—Diphtheria toxin antitoxin mixture (see New and Non-official Remedies, 1923, p. 284), each c.c. representing 3 L+ doses of diphtheria toxin neutralized with sufficient antitoxin to conform to the toxicity requirements of the U. S. Public Health Service. It is marketed in vials containing, respectively, 1 c.c. and 50 c.c., and in syringes containing one immunizing treatment. Cutter Laboratory, Berkeley, Calif.

Anti-Anthrax Serum for Human Use-Cutter.—An anti-anthrax serum (see New and Non-official Remedies, 1923, p. 287), marketed in double-ended vials containing 50 c.c. for intravenous injection. Cutter Laboratory, Berkeley, Calif.

Rabies Vaccine-Pasteur (Cutter).—An anti-rabic vaccine (see New and Non-official Remedies, 1923, p. 294), prepared according to the method of the Hygienic Laboratory of the U. S. Public Health Service. The emulsion from the cord is shipped daily and is diluted at the time of injection. The treatment consists of 21 daily injections. Cutter Laboratory, Berkeley, Calif.

Diphtheria Toxin for the Schick Test-Cutter.—A diphtheria immunity test (see New and Non-official Remedies, 1923, p. 323), marketed in packages of two vials, one containing diphtheria toxin and the other physiologic solution of sodium chloride for dilution. Cutter Laboratory, Berkeley, Calif.

Capsules Carbon Tetrachloride (Human Use)-P. D. & Co.—A brand of carbon tetrachloride-N. N. R. It is marketed in capsules containing 20 minims. Parke, Davis & Co., Detroit.

Elixir of Veronal.—Each fluid drachm contains veronal (see New and Non-official Remedies, 1923, p. 63), 2 grains in a menstruum containing alcohol 33.5 per cent. Winthrop Chemical Co., New York.

Diphtheria Toxin-Antitoxin Mixture (New Formula)-Squibb.—Diphtheria toxin-antitoxin mixture (see New and Non-official Remedies, 1923, p. 284), containing in each cubic centimeter 0.1 L+ dose of diphtheria toxin neutral-

ized with the required amount of diphtheria antitoxin. Marketed in packages of three vials, each containing 1 c.c.; and in vials containing, respectively, 10 c.c. and 20 c.c. of the mixture. E. R. Squibb and Sons, New York. (Jour. A. M. A., December 22, 1923, p. 2115.)

PROPAGANDA FOR REFORM

Liquid Petrolatum as a Laxative.—Liquid petrolatum is indigestible. It is not absorbed, and, therefore, cannot produce poisoning. In ordinary quantities the administration of liquid petrolatum does not seriously impair the alimentary efficiency. Like all laxatives used in very large quantities, liquid petrolatum may diminish the degree of utilization of food by promoting evacuation before the functions of digestion and absorption can be entirely completed. Liquid petrolatum may produce gastric distress and, therefore, should be taken in a way to interfere least with gastric digestion by administration before bedtime or an hour before meals. In reporting on a proprietary brand of liquid petrolatum widely exploited to the public, the Council on Pharmacy and Chemistry warned that constipation should be treated by dietary and hygienic means, as evacuants are but temporary measures. It further cautioned that liquid petrolatum is medicinal: it modifies greatly the intestinal flora; it acts as a lubricant and emollient; it modifies the absorptive powers of the intestinal mucous membrane; it is capable of influencing the digestion of fats; and, in short, liquid petrolatum is a drug, the indiscriminate and excessive use of which should not be encouraged. (Jour. A. M. A., December 1, 1923, p. 1896.)

Spahlinger Treatment for Tuberculosis.—Spahlinger is a resident of Geneva who received medical training but took his degree in law. Later he abandoned law for research work. The Spahlinger treatment makes use of vaccine and serum therapy. The theory from which the treatment is evolved is that the tubercle bacillus emits different toxins under varying conditions of temperature, environment, etc. Many of these are claimed to be isolated as either exotoxins or endotoxins. The vaccines—of which there are said to be about twenty—are used for prophylaxis for treatment of the milder cases of tuberculosis and for the production of the various serums used in the treatment of the more severe cases. It has been reported that the British ministry of health is prepared to encourage the experimental trial of the Spahlinger preparations under scientific supervision. The British Red Cross has appropriated money to enable Spahlinger to work on a larger scale in the production of his preparations. The reports in regard to the efficacy of the preparations which have appeared in British medical journals are conflicting, and the Red Cross organization has made it clear that the products are in the experimental stage. (Jour. A. M. A., December 1, 1923, p. 1896.)

The Galvano Method for Goiter.—In the cheap and not too particular rural weeklies, advertisements have appeared for the "Galvano Necklace," said to be "the latest discovery for the relief or cure of goiter by mild electrical treatment." The device is advertised by the Cosmas Pharmacal Co., Watertown, Wis. The advertising for this device stresses the fact that the U. S. Patent Office has granted a patent on it. The public does not know, of course, that the U. S. Patent Office has granted patents on many pieces

of medical pseudoscience. According to the patent specifications, the Galvano Necklace consists of beads made of glass, or other insulating material, between which are placed, alternately, small zinc and copper disks. Through the disks and beads run a metallic wire. The alleged purpose of the invention is that of "generating galvanic currents in contact with the skin in the presence of mercurous iodid and calcium chlorid." In use, an ointment containing mercurous iodid and calcium chlorid is applied to the skin of the neck, and the necklace is hung so that the zinc and copper disks will come in contact with the anointed skin. That this device has decided value in the treatment of goiter is unthinkable. Young women with physiologic enlargement of the thyroid will, doubtless, continue to purchase the device and as the enlargement disappears, as it normally does, will furnish testimonials for the promotion of the device. (Jour. A. M. A., December 8, 1923, p. 1974.)

Santoperonin.—According to Professor Heubner, the history of Santoperonin, claimed to be an ascaricide, does not arouse confidence. The proprietary was placed on the German market before satisfying the requirements that should govern the introduction of new medicaments. Its composition has varied; the exploiter has maintained an air of secrecy concerning the identity. Examination indicated that it was a mixture of copper oxid with organic material which consists essentially of aromatic compounds. There seems to be little clinical evidence to warrant its use. (Jour. A. M. A., December 15, 1923, p. 2055.)

"A" Formula or "The" Formula?—When the proprietary evil in the United States was at its worst, a common piece of advertising deceit was that of the fake formula. On its face, such a "formula" was impressive—at least to those who were not chemists. After the American Medical Association created its own chemical laboratory, the Association chemists demonstrated repeatedly the absurdity of the seriocomic chemistry of some of the pharmaceutical manufacturers. It was not long before the crude chemistry and cruder dishonesty of pharmaceutical concerns began to disappear. Yet today there are still a few firms which endeavor to lend plausibility to their wares by resurrecting old methods. The report of the Council on Pharmacy and Chemistry on Gly-So-Iodonate brings out that a formula, both qualitative and quantitative, appears on the label of the preparation. The formula is absurd and impossible, and the A. M. A. Chemical Laboratory found that some of the ingredients were not present in the amount claimed. (Jour. A. M. A., December 22, 1923, p. 2118.)

Does Heat Injure Vaccines?—It is generally believed that vaccines lose in potency on standing at room temperature. But, so far as known, the sterilization of vaccines by heat does not injure the antigenic potency any more than other methods of sterilization, e. g., chemicals. The astounding deduction of a manufacturer of vaccines that heat sterilization, at a definite temperature for a given time, must be highly injurious, because vaccines lose in potency on standing for weeks and months at variable room temperature, is simply a pseudoscientific statement intended presumably to bolster up the merits of the advertised wares in the eyes of the more or less thoughtless purchasers. (Jour. A. M. A., December 22, 1923, p. 2135.)

PROCEEDINGS OF THE MINNESOTA ACADEMY OF MEDICINE

MEETING OF DECEMBER 12, 1923

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, December 12th, 1923, at 8 P. M. The President, Dr. A. S. Hamilton, called the meeting to order. There were 30 members and one visitor present.

Dr. J. T. Christison read the following memorial of the life of Dr. Warren A. Dennis, a former president of the Academy:

Dr. Warren Arthur Dennis was born in Walworth County, Wisconsin, December 5th, 1869. His death occurred in St. Paul, November 8th, 1923, after a protracted illness, from pneumonia. He is survived by his wife and six children.

He was a graduate of the University of Wisconsin in 1891, receiving the degree of B.L., later entered the medical school of the University of Minnesota, graduating in the class of 1896. After serving an internship of one year in the City and County Hospital in St. Paul, he became associated with the late Dr. C. A. Wheaton, one of the most highly respected surgeons of his day.

His professional life was devoted almost exclusively to the practice of surgery, in which branch of the profession he was regarded as a master. While excelling in his own specialty he always showed a keen interest in all branches of medical science. It was this outstanding quality that endeared him to his medical friends and associates, and helped in cementing friendships which were so enduring. His frank, sympathetic nature won him the everlasting esteem and reverence of his patients, to whom he was untiring in his efforts to serve.

Dr. Dennis enjoyed an enviable war record, having served in the Spanish-American war as a major. During the late war he attained the rank of Lieutenant-Colonel, serving with the 88th Overseas Division where he did notable work in brain surgery.

While leading a very busy life, Dr. Dennis was of a studious nature and was well versed in the latest problems of surgery. He was active in the many medical and surgical societies to which he belonged, and was prominent as an officer in most of them. An active attendant and frequent contributor to all of these organizations.

Our friend and confrere has departed, but we shall ever cherish the noble attributes of one so dearly loved and respected by a sorrowing family, a bereaved profession and a saddened public.

Signed: J. T. CHRISTISON
C. N. McCLOUD
FRANK E. BURCH.

The following candidates were elected to membership in the Academy: Dr. Wm. R. Murray (Minneapolis) and Dr. Carl B. Drake (St. Paul) were elected as active members,

and Dr. W. A. Coventry of Duluth, and Dr. M. S. Henderson of Rochester, were elected associate members.

There were no papers given at this meeting, but the following members reported cases:

1. DR. WM. LERCHE (St. Paul) showed lantern slides of several cases of suppuration in the posterior mediastinum that he had operated upon, and also cases of esophageal and tracheal fistulæ following mediastinal suppuration.

In connection with these cases, Dr. R. E. Scammon discussed the anatomy of the neck and mediastinum, and its embryological development.

2. DR. HENRY L. ULRICH (Minneapolis) reported a case of bilateral hydronephrosis and hydroureter of unknown origin. Gross specimen shown.

C. R., white, male, chauffeur, age 18. Was first admitted to the hospital on Oct. 14, discharged on Oct. 19th, readmitted on the 21st, and died on the 28th.

The family history was thought to be of some importance in that one of his brothers has talipes equinus and one sister has achondroplasia. The rest of the family was said to be normal. The patient had a number of the childhood diseases; was ill for 3 months at the age of 12 with typhoid fever and a so-called "blood poisoning" at the age of 13, at which time he was ill for 6 months. Although the patient stated that prior to the onset of the present illness he had been well, subsequent investigations showed that he had not been able to do his work in the usual manner for possibly 1 to 2 months previously. On Oct. 1st he was awakened from his sleep with diffuse cramps throughout the abdomen. This distress interfered with his sleep and continued, though less severe, up to the time of admission. On Oct. 2nd, he became nauseated and vomited, and this persisted during a period of 2 weeks. All his symptoms were less severe when in bed. A yellowish discoloration of the skin was noted at the beginning of the illness. In the interval between his discharge and second admission, it was said that he had been unconscious for a few minutes at one time. He was more thirsty than usual and had passed what he thought to be a greater quantity of urine than normal. Cramps in the legs occurring at night during the past 4 years was another symptom complained of.

On physical examination, the patient was found to be fairly well-developed and some under-nourished. Appeared much older than the age given. Mentality seemed below par. The skin and mucous membranes were pale. There was no cyanosis and there was thought to be some jaundice of the sclerae. There was no edema. The submaxillary and anterior cervical glands were palpable. The peripheral arteries were soft. The pulse was regular and of good quality. Blood pressure was 118/90. During observation, the highest systolic blood pressure was 126 and the highest diastolic was 90. The hand was large and angular in appearance. The hair was sparse; the pupils were equal, regular and reacted normally to light and accommodation. No nystagmus. Pyorrhea alveolaris present. There was a diffuse bilateral enlargement of the thyroid. The thorax was symmetrical. Harrison's grooves present; a slight impairment of tactile fremitus and diminished vesicular breathing noted over the left lower lobe posteriorly. No other physical findings made out in the examination of the lungs.

There was no bulging of the precordium and no visible cardiac impulse. A definite thrill or rub was noted on palpation over the precordium. The percussion dullness of the heart measured 2.5 cm. and 9 cm. to the right and left of the midline respectively. On auscultation, a harsh to-and-fro friction sound corresponding to the palpable thrill mentioned was heard during all phases of respiration.

There was no evidence of valvular disease. The vascular signs associated with adherent pericardium as well as the retractive phenomena were not observed. There were no abdominal masses. Abdominal muscles were tense at all times. The bladder was not found to be enlarged.

On admission, it was thought that an intention tremor, an ankle clonus, speech disturbance and Babinski (left) were present. None of these signs except his slow speech was apparent or found while on the ward. He was generally hyper-aesthetic and the tendon reflexes were hyperactive. Fundus examination was normal.

A number of urinalyses showed specific gravity 1010-1012; reaction, usually acid; albumen, heavy traces, 1 plus, —3 plus. Many pus cells and an occasional red cell. No casts were seen on any examination. There was no bile in the urine. On the days that the intake and output of fluid was measured, it was found that he was taking in about 700 c.c. and excreting about 400 c.c. of urine. No incontinence of urine. The phenolsulphonephthalein tests on several occasions showed no return of the dye..

The blood examination shows—hemoglobin 42 per cent, R.B.C. 2,440,000; W.B.C. 8,900; differential count and morphology normal. Later the hemoglobin was 37 per cent, 2,060,000 erythrocytes and 9,300 leucocytes. The Wassermann reaction was negative. The blood creatinin was 8.3 mgs. per 100 c.c. The urea nitrogen 221 mgs.; the blood sugar 17 per cent. Later the creatinin was 8.8 mgs., the urea nitrogen 244 mgs., uric acid 9.6 mgs. Alkali reserve 20.

The x-ray of the heart was taken at a distance of 6 feet and reported as cardiac hypertrophy and dilatation. The outline suggested a hypertension type. The sella turcica was reported as very small and plates of the kidneys were reported as normal in size, shape and position. The temperature varied between 96 and 99. The pulse usually about 90 and the respiration not more than 24.

The patient's breathing became labored. At times an uremic odor was noted on the breath. He became more and more drowsy, delirious, and finally comatose. He had frequent nose bleeds and vomited. Apparently his hearing was impaired. Toward the last a cardiac irregularity was noted, with increased rate up to 128. A cystoscopic examination was requested but not made.

The patient died October 28th. The clinical diagnosis was:

1. Acute fibrinous pericarditis
2. Renal insufficiency.

The post-mortem revealed a double hydronephrosis, double hydroureters. The ureters were enormously enlarged and there was very little kidney tissue left, only one pole of the right kidney. The bladder was slightly dilated. It looked like a paralytic bladder. There was absolutely no obstruction anywhere in the urethra to account for this dilatation.

Comment: This boy was evidently suffering from congenital hydronephrosis, and the remarkable thing about this case is that he should have lived to be 19 years old. I am only acquainted with one similar case of which the explanation was that the condition was due to multiple sclerosis. At least, this disease was associated with similar findings. This boy's spinal cord was negative as far as sclerosis was concerned, so we will have to attribute this boy's condition to a congenital lesion.

DISCUSSION

DR. OWRE: I saw this case at post-mortem, and there was absolutely nothing to account for the hydronephrosis. I cannot account for it unless it was congenital, and yet pathologists tell us there is no such thing. I had one case several years ago, of a boy 14 years of age, in which I took out the kidney and ureter, and the ureter was greatly enlarged.

DR. FARR: Last year Dr. Brown, of Detroit, Mich., reported about 100 autopsies on children or embryos that he had collected, with 66 per cent malformations of the genito-urinary tract. He described every deformity of the kidney and ureter that I have ever seen, or heard of, or read about.

DR. A. E. BENJAMIN (Minneapolis) reported three cases of diseased thyroid in one family. Mother and two daughters. Two toxic thyroids, one colloid with toxic symptoms.

CASE 1. Mrs. E., age 50, housewife, weight 150. Generally well.

Complaint: Enlarged and troublesome thyroid for about 20 years. Quite nervous.

Complete history record not found.

Examination: Thyroid enlarged. Right lobe the size of an orange; left half as large.

Diagnosis (preoperative): Cystic goitre.

Treatment: Operation 9-4-1913. St. B. Incision—collar. Sterno-thyroid and sterno-hyoid muscles clamped transversely and severed. Superior and inferior blood vessels of lobes clamped with forceps. Diseased interior portion of lobes removed, leaving most of the capsules. Blood supply ligated with chromic catgut. Capsule and remaining portions stitched with plain catgut. Muscles and fascia were stitched with chromic catgut. Small rubber drain inserted.

Specimen: Portion removed contained colloid material. Some cysts. Degenerating and hemorrhagic areas.

Results: Pulse rapid for a time but recovery was complete and patient has been well ever since operation.

CASE 2. Mrs. L. (daughter of case 1), age 24, housewife, married one year, no children, weight 100.

Complaint and Symptoms: Perspires considerably. Extremely nervous and trembly and rapid pulse, especially upon exertion. Nauseated and vomited, and bowels loose. Appetite irregular. Loss of flesh and symptoms progressed. Pulse 120-160. Was kept in a country hospital until symptoms subsided and was then removed to Minneapolis, where special diet, sedatives and general good care were given.

History: Family history negative except that mother was operated on for colloid cystic goitre in 1913. Personal history—usual children's diseases. Scarlet fever at 7 years. Influenza in 1920. Menstrual history—onset at 15 years; painful and scanty; missed last two months.

Examination: Head—enlarged turbinate, protrusion of eyeballs and uncertain vision. Tonsils irregular, not diseased. Right thyroid enlarged twice normal size. Thorax normal except rapid heart. Abdomen practically normal. Pelvis: slight retrocession of uterus, some enlargement of left ovary and prolapsed. Extremities: unsteady and trembling hands. Urine negative, hemoglobin 70 per cent, blood pressure 138/70, temperature 98.6-100.6. X-ray treatment for enlarged thyroid with little improvement.

Diagnosis: (Preoperative) Exophthalmic toxic goitre.

Operation: 1. Sept. 21, 1920. Anesthetic, local. Pulse 160. Upper pole of right thyroid ligated. Patient was very nervous and excited during the procedure, which symptoms continued for several days. Sept. 24, 1920, pulse 118, condition good.

2. Oct. 12, 1920. Local anesthetic and some gas. Blood vessels of both lobes ligated and the right lobe resected. Patient was very nervous at the time of operation and vomited considerably following it. Her condition gradually improved and she left the hospital Oct. 23, 1920. Condition good, and pulse 130-140.

3. May 21, 1921. Anesthetic—gas and novocaine were used. Pulse between 160 and 128 during operation. A complete removal of all diseased tissue on the right side was done. There were many adhesions present from former operations. Plain catgut passed back and forth through the capsule to control hemorrhage. Pulse when she left hospital 100. In good condition.

Section from thyroid: Many large dilated acini, containing colloid. The epithelium lining the acini is low cuboidal type. There are also a number of solid masses of cells in which the epithelium appears more cylindrical and active.

Diagnosis: Mixed goitre, colloid and toxic adenoma.

Results: Patient made a gradual recovery. Gained in weight and has been in good health since, excepting a little nervous, caused from disturbance of an abscessed tooth.

Oct., 1923: Blood pressure 138/100. Pulse 130. Weight 125. Hemoglobin 85 per cent.

CASE 3. Miss E. (daughter of Case 1), age 22, household duties, weight 115. Noticed neck was swollen and painful to pressure. Very nervous.

History: Family history negative except mother—colloid cystic goitre; sister—mixed colloid and toxic adenoma.

Patient has been quite well. Frequent frontal headaches, eyes rather weak but never examined. Sore throat frequently; tonsillitis once. Heart quite rapid the last few weeks. Appetite good, digestion good, bowels regular. Menstruation normal.

Examination: Nose—some redness inside. Some inflammation of tonsils, left embedded. Right thyroid three times normal size. Cardiac pulsation, very rapid. Abdomen and pelvis negative. Urine negative, blood pressure 140/60, temperature 99.6, hemoglobin 80 per cent. W.B.C. 7,300. Basal metabolism +57, pulse 110-140.

Diagnosis: Exophthalmic goitre.

Operation: 1. April 22, 1922. Anesthetic—novocaine and gas. Right inferior artery ligated with plain catgut No. 1. Left inferior artery ligated. Right superior artery ligated. Part of central portion of right lobe included in addition suture. Pulse when left hospital 110-120. Improved. June 6, 1922, temperature 99.8, pulse 132, weight 97½, generally

well, but quite nervous. Sept. 13, 1922, temperature 99.4, pulse 90-100, hemoglobin 75 per cent, blood pressure 135/70. Still quite nervous.

2nd operation. Sept. 16, 1922. Anesthetic—gas and ether. Pulse 118-120 before operation. Respiration 28. Three-fourths of right lobe removed, removing inner diseased portion. Hemorrhage controlled by plain catgut suture back and forth. Gradually improved and left hospital in fairly good condition, but somewhat nervous. Pulse 98. Oct. 18, 1922, temperature 99.2, pulse 140-160, weight 106½, hemoglobin 80 per cent, blood pressure 130/76, looks well, feels good. Feb. 28, 1923, examination showed slight mitral stenosis. Thyroid considerably enlarged and soft. Operation postponed until in better condition. Basal metabolism +18.

3rd operation. April 20, 1923. Anesthetic—local and gas. Pulse before operation 120. During operation 160-140. Most of inner left thyroid removed. Capsule stitched with plain catgut. There were many adhesions present. The right thyroid was about normal size. Discharged from hospital May 3, 1923. Condition good. Pulse 110.

Specimen: April 20, 1922, hypertrophy of thyroid.

Results: Patient improved very much. Oct. 16, 1923, blood pressure 130/74, pulse 90, weight 116½. Feels very well.

Owing to the lateness of the hour no further cases were reported.

The meeting adjourned.

JOHN E. HYNES,
Secretary.

TRANSACTIONS OF THE MINNEAPOLIS SURGICAL SOCIETY

STATED MEETING HELD DECEMBER 6, 1923, THE PRESIDENT,
J. M. HAYES, IN THE CHAIR

DR. J. FRANK CORBETT: I have a rather interesting case of rupture of the middle meningeal artery. Rupture of the middle meningeal artery is a comparatively common thing, but we usually expect a certain sequence of symptoms. We have an individual who has been struck on the head, who is perhaps momentarily unconscious but after a few seconds recovers consciousness, walks and talks and acts as usual, then after six or eight hours, on careful examination, we find certain changes have taken place. The reflexes are relatively quickened at first. Then at a little later period we find a flaccid paralysis and perhaps aphasia, and a little later complete unconsciousness and interference with respiration and other medullary symptoms. That is the classical picture of hemorrhage from the middle meningeal artery, a progressive condition.

It is not the only form under which we encounter this condition, and this patient that I bring before you tonight—she has kindly offered to come here—is unusual in that within five minutes of the time that she was struck with an automobile she was completely unconscious. When I saw her in the hospital she was not only completely unconscious, but the respiratory centers were seriously involved. It

looked as though death was almost certain. On examination I found extreme choking of the discs; the patient was in shock; failure of respiration was imminent. That led me to at once open into the head, and I found an enormous hemorrhage around the middle meningeal artery. I emptied this clot out and ligated the artery as quickly as I could and got the patient back to bed. The next day she was paralyzed on one side and had a complete aphasia. This paralysis lasted for about a week and the aphasia began to improve after seven days. I think you will see before you a perfectly normal child in body and mind. She has gone back to her school work and is making progress.

The only excuse I have for bringing this case before you is the fact that it was a case where an immediate operation was clearly indicated and yet the picture was perfectly atypical.

DISCUSSION

DR. H. B. SWEETSER: How long after the injury was it before you operated?

DR. CORBETT: I operated immediately. I think I saw the child within two hours after the accident.

DR. BAXTER: Had the blood clotted?

DR. CORBETT: Yes, there had been some clotting of the blood.

DR. MAXEINER: What were the landmarks?

DR. CORBETT: Well, the middle meningeal starts at the foramen spinosum, traverses the middle cranial fossa upwards and forward. You may have a rupture anywhere; the typical place is an inch and a half above the zygoma and an inch and a quarter behind the external angular process. However, it may be ruptured any place.

DR. H. B. SWEETSER: Did you find any cranial fracture?

DR. CORBETT: Yes, there was a fracture of the skull. It cut this artery off. The artery must have been unusually large and the hemorrhage very rapid. That is why we had the early appearance of symptoms.

DR. M. F. LYNCH: Case report of ovarian tumor with twisted pedicle in child of ten years.

This patient was first seen by me at her home in this city about 9 P. M., Saturday, August 17, 1923, and the following history obtained:

The family history is unimportant. The parents are healthy, and have two children, the patient, aged ten, and a younger sister, aged seven.

Personal History.—Patient was a full-time, well-developed baby. Labor normal. Mother nursed her for six months. When the patient was two days old, there was a bloody discharge from the vagina, which lasted for four or five days. There was no bleeding from the mouth, bowel or navel, and the child was not ill. The mother stated that the child developed normally, and has been healthy except for the following diseases of childhood: Whooping-cough at two years, and measles at three years. She has had several mild attacks of acute tonsillitis, and had "flu" in 1918. She has always had slight constipation.

Since April of this year she has had repeated attacks of mild abdominal pain. These attacks have generally come on a short time after eating, and were relieved by laxatives. These attacks have recurred from two to three weeks apart,

sometimes the pain was associated with vomiting, but more often she did not vomit.

Habits: Appetite good. Sleeps well. Healthy, happy child, up to normal weight.

Present Complaint.—Saturday, August 17, 1923, shortly after the noon-day meal, she was taken with cramp-like pains in the lower abdomen. She vomited repeatedly, and was very restless during the afternoon and evening. There had been no movement of the bowels that day, but during the afternoon she went frequently to stool, without result.

Examination.—Patient is a fairly well-nourished child, tossing about the bed in great discomfort. The face is flushed, the skin clear and moist with perspiration. Pupils are equal, and react normally. Teeth are in good condition. Tonsils are somewhat enlarged, but show no active disease. Movements of the head and neck are normal, and no palpable cervical glands found.

Chest: The chest is rather long and narrow. No tenderness on palpation. Normal heart dullness. No indication of disease of heart or lungs.

Abdomen: The abdomen appears somewhat distended. No visible peristaltic waves. The umbilicus protrudes somewhat, but no hernia is present. The abdominal muscles are rather tense and alike on both sides. The only definite tenderness is at a point corresponding to McBurney's point, but on the left side. This is constant on repeated examinations. No mass or dullness can be brought out by percussion. Palpation about the kidneys and spleen negative. Liver dullness is normal, and costal margin cannot be felt. Both groins are negative for hernia or adenopathy. The temperature at this time was 98; pulse, 80 and of good quality.

Diagnosis and Treatment.—The patient had just returned from a two weeks' camping and motoring trip, and when she was somewhat relaxed by a suds enema, it was thought her trouble might be due to a food disturbance. The following morning I saw her again. She had had a very uncomfortable night, and slept but one short interval. Her temperature was normal, pulse 90, and she had developed considerable rigidity of the abdominal muscles. This was most marked on the left side, with the same point of tenderness as before.

A rectal examination was made at this time, but was unsatisfactory. An indefinite resistance could be felt in front and above the rectum. Enema of milk and molasses produced a free evacuation of the bowel, and ruled out a true obstruction. The pain and discomfort was not relieved, and later she developed a constant desire to urinate.

A diagnosis of a possible obscure appendicitis, diverticulitis or volvulus was made, and immediate operation advised. She was admitted to St. Mary's Hospital, and operated upon the same day.

Pre-operative laboratory findings were: Urine—clear, sp. gr. 1.025, acid reaction, no sugar, no albumin, microscopic negative; blood-leucocytosis 19,850, no differential made.

Operation.—The abdomen was opened under gas and novocaine anesthesia, with right rectus incision near the mid-line. There was a small amount of free fluid in the peritoneal cavity. The transverse colon hung low across the abdomen. The appendix was free and quite normal in

appearance. When the pelvic organs were exposed, the right tube and ovary appeared normal, and led the way to a small uterus. There was a dark necrotic mass behind the uterus about the size of a small grapefruit, and filling the brim of the true pelvis. When this was lifted up, it exposed a pedicle that was twisted four or five times in itself and embraced the left tube, which was also necrotic. There were no adhesions present. The pedicle was tied off with the left tube and the stump turned in against the left broad ligament. The tumor appeared to be a simple unilocular cyst that involved the whole left ovary. The outer covering was smooth, the wall rather thick, and the cyst filled with fluid.

The wound was closed without drainage. She made an uneventful recovery, and was discharged from the hospital on the seventh post-operative day.

Pathological Report.—The following report was furnished by M. Schelender, director of the laboratory at St. Mary's Hospital:

"Doctor E. T. Bell, of the University Medical School, has kindly examined the specimen and microscopic slides with this result: Ovary is 10 cm. in diameter, consists of single large cystic cavity 9 cm. in diameter, walls $\frac{1}{2}$ cm. thick. Contents—dark red and hemorrhagic in appearance, semi-fluid consistency, not definitely oily. No teeth visible; no hair recorded. Walls appear smooth."

A microscopic section through the wall showed a layer of stratified squamous epithelium with cornification of the free surface, many hair follicles and a few sweat glands beneath the epithelium. Extensive diffuse hemorrhage was present throughout the wall in many places. Small muscles were seen attached to the hair follicles.

Diagnosis: Dermoid cyst.

As to the frequency of dermoids, Ewing states they constitute about 10 per cent of all ovarian tumors. They appear at all ages, often in childhood, but most frequently between the ages of thirty and forty.

F. W. Lynch, in his work on pelvic neoplasms, quotes the following authors as to frequency of dermoids:

Olshausen, 4 per cent (in 2,275 ovarian tumors).

Howard Kelly, 18.8 per cent.

Sawyer, 18.7 per cent.

Mayo Clinic, 10 per cent (about).

DISCUSSION

DR. H. B. SWEETSER: I would like to ask Dr. Lynch what percentage of cases have a twisted pedicle, if he has looked that up.

DR. LYNCH: It seems that quite a large percentage come to operation on account of complications, and that is one of the commonest complications. I do not know the exact percentage, but I know that in the London Lancet for April of this year there is a case reported of a dermoid cyst in a fetal head in an infant of five months, with a twisted head that strangulated the uterus. It is a common complication, and it is a thing that seems to bring the children to operation.

DR. S. R. MAXEINER: I am going to give you only a very few words on this case, but I thought it was interesting to present. It is a boy of twelve; family history is negative;

previous diseases are negative. Last Friday, the 30th of October, he was hunting near Savage, with a playmate, when a .22 rifle was accidentally discharged and a bullet entered his abdominal cavity. The wound was about two inches above and just to the right of the navel. We took him to the x-ray room and localized the bullet in the lower left quadrant of the abdomen posteriorly. Localization and the x-ray plate showed that the bullet had penetrated the ilium and was lodged in the left buttock. He was taken to the operating room and given hypodermoclysis. Before we started, his condition was reasonably good. He was matched for blood transfusion, but this was found to be unnecessary. The abdomen was opened by a vertical incision through the left rectus muscle, because the bullet had taken a course toward the left pelvis. On opening the abdomen we found the ileum in about its mid-portion was penetrated through and through, making two perforations. The bullet then passed across the abdomen and made an in-and-out perforation of the descending colon. The perforation in the descending colon was both on the anterior and posterior surface, the posterior one being retroperitoneal. The ileum was so torn that in the repair of the bowel it virtually resulted in an end to end anastomosis. In repairing the sigmoid the peritoneum on the outer side was divided and the descending colon was rotated so as to preserve its blood supply, and the repair was made from the posterior surface.

The pelvis was drained; a drain was inserted behind the colon into the retroperitoneal space, and another drain along the outer side of this colon; a fourth drain directly into the abdominal cavity. It is six days tonight at just about this time that we operated upon him. I will show you the temperature and pulse record. His temperature and pulse records are both normal now. He was done under local anesthesia, absolutely without pain. The child's condition was fully as good at the close of his operation as it was at the beginning.

He had peritonitis as we expected, and the abdominal wall showed some rigidity and a very slight distention. This is entirely gone now, and there is only one drain remaining at this time.

DISCUSSION

DR. RISHMILLER: What size bullet was it?

DR. MAXEINER: Twenty-two.

DR. BAXTER: I would like to ask Dr. Maxeiner how he located the perforation in the extraperitoneal portion of the descending colon.

DR. MAXEINER: I had localized the bullet before hand and marked the skin with the vertical ray from the x-ray and also its depth. I had these marks to go by and I knew where the bullet was. I knew its course absolutely. We had the perforation on the free peritoneal side and I knew that there must be one on the other side. I simply freed the colon so that I could expose the posterior surface of it and rotated it over and it came directly in view. The perforation on that posterior surface was very small.

Paper of the evening given by Dr. Brophy, Chicago: "Fundamental principles and recent conclusions in surgery of congenital cleft palate." (Paper and discussion to appear in MINNESOTA MEDICINE at a later date. Ed.)

ENDOCARDITIS LENTA: Carey F. Coombs (Quart. Jour. of Med., July 1923). This article is based upon 30 cases of chronic ulcerative endocarditis. Males predominate (29 of the 30 cases). The average age was 30.6, the extremes being 20 and 44. A history of rheumatic infection was present in only 11 of the 30 cases, quite in contrast to previous considerations. These patients had, however, a striking etiological factor in the excessive fatigue occasioned by strenuous military service. No particular route of infection was determined nor could much be made of the figures indicative of lowering of resistance by general infections. Almost without exception the condition developed in men of fine physique, who had exerted themselves to the utmost of their physical powers. The possibility of an increased lactic acid content of the blood making a more favorable media for the invading micro-organism is suggested (reference to Walker Hall, Jour. Path. and Bact., Cambridge, 1922, XXV, 19 and 297).

The aortic valves, rather than the mitral, were attacked with remarkable consistency. The organisms were few in number, difficult to find (those that have been found, non-hemolytic streptococci), and difficult to cultivate on artificial media. The vegetations themselves were not very productive; the valves often much sclerosed and with considerable deposits of lime. Little or no polymorphonuclear infiltration was present, the reaction being rather proliferative in character. Renal changes brought about by emboli were generally present. No evidence of previous cardiac infection was found in most cases. Blood cultures were consistently negative.

Symptomatology: The course of the disease was extremely insidious; general loss of flesh and strength; pallor; dyspnea. Many of the patients for a long time refused to consider themselves ill. The ill health may be apparent for months before physical signs relating to the valve develop. Enlargement of the spleen noted in 52 per cent; slight and occasional rises of temperature in 61 per cent; petechiae were found in 50 per cent; red blood corpuscles in the urine in 54 per cent; albumen in urine in 65 per cent; anemia; clubbing of fingers. Retinal hemorrhages were noted in three cases. The slow course of the disease was illustrated by one case, the duration of which was three and one-half years. Treatment was of no avail.

A previous article on Chronic Ulcerative Endocarditis by the same author appeared in the Quart. Jour. of Med., 1921-22, XXV, 114.

T. A. PEPPARD.

THE MODERN METHODS OF TREATING LOBAR PNEUMONIA: Henry M. Thomas, Jr. (Amer. Jour. of Med. Sc., Dec. 1923.) Thomas' recommendations may be summarized as follows:

In view of the sharp, sudden and severe type of toxemia of lobar pneumonia, and with its relatively short duration, a reasonable, wholesome diet, without any undue restrictions, is indicated. Three to four thousand c.c. of fluid should be administered daily in order to favor elimination, and in the event of vomiting or delirium liquids by mouth should be supplemented with subcutaneous injections or a slow proctoclysis. Absolute bed rest should be insisted upon, and no active movements allowed on the part of the patient. The physician and nurse should insist on absolute obedience in this respect.

The question of digitalis, Thomas does not answer very emphatically, although he believes that digitalis is indicated to the limit of threshold digitalization, and is urgently indicated with the first evidence of myocardial insufficiency. If sudden heart failure intervenes the use of morphine and atrophine, or even venesection, is admissible. If additional stimulation is required, caffeine sodium benzoate and camphor in oil are available stimulants. Careful hydro-therapeutic measures, in the form of sponging every few hours, are of value, but one must not employ it ill advisedly. For the abdominal distention occasionally found as a result of the severe toxemia, turpentine stupes, high rectal tubes or turpentine enemata are of value, and pituitrin may be supplemented hypodermically to reduce it. It may be necessary in obstinate cases to eliminate milk from the dietary. In early cases when pain is a troublesome symptom, morphine is frequently required in small doses, and an ice bag may be applied locally, or a tight chest binder. The administration of oxygen is of value if cyanosis and dyspnea become prominent symptoms. Fresh, cool air is of proved value.

In discussing the specific therapy, the writer states that the Type I pneumococcus serum as developed by the Rockefeller Institute is the only one that has received enough of a trial to warrant discussion. Kyes' chicken serum proved of value with the Cook County Hospital, where a reduction in the mortality rate from 45.3 to 20.8 per cent was brought about, but no further statistics are available. The immune serum from convalescent patients, as suggested by Dr. Stengel, is attended by technical difficulties and also by theoretical objections. Prophylactic vaccination with the killed cultures of Type I, II and III pneumococcus seems to be of value in lessening the incidence of respiratory infections and pneumonia, as well as their severity. Thomas believes that hypodermic injections of quinine in high solutions are of value as a specific chemical agent, and he wishes to call attention to a quinine derivative prepared in Germany under the name of "Numoquin," which he believes may prove to be a valuable adjunct to our armamentarium. In his experience, and from his review of the literature, he believes that the Type I pneumococcus serum is of value in lowering the mortality rate.

FRACTURES OF THE ELBOW JOINT AND OF THE LOWER END OF THE HUMERUS: Edgar Lorrington Gilcrest (Surg., Gyn. and Ob., Vol. 37, October 1923). In treating fractures of the elbow joint and lower end of the humerus the anatomical relations should be borne in mind and the x-ray should not be solely relied upon to give us information of the anatomical deformities.

In children fractures in this location are often the result of indirect violence, and in the adult of direct violence. Ten varieties of the lower end of the humerus are mentioned:

1. Supracondylar (over one-third of cases of fractures of lower humerus).
2. Diacondylar.
3. Intercondylar (frequently compound, usually in adults due to direct violence).
4. Separation of the lower epiphysis (very infrequent; occurs in childhood).
5. External epicondyle (rare; result of direct violence).
6. External condyle (occurs in about 17 per cent, frequently in children).
7. Internal epicondyle (usually occurs from hyperabduction of elbow fully extended).
8. Internal condyle (unusually rare).
9. Capitellum (only seventeen cases reported in literature).
10. Trochlea.

The fully flexed position with bandaging to chest is the treatment for fractures in the vicinity of the elbow joint, with the exception of fractures of the olecranon process, for the following reasons:

1. It gives the most complete anatomical reposition of fragments and the best fixation.
2. It favors the retention of the more important flexion function of the joint.
3. It co-operates with gravity in the subsequent restoration of function.

The elbow is slowly but firmly flexed after reduction is established by strong traction on the forearm with the elbow fully extended and supinated. After two weeks the forearm can be lowered a few degrees a day and passive motion is started in about four weeks. Any pain production from these procedures should indicate rest in corrective manipulations.

Fracture of the olecranon process is due to direct injury and is frequent in adult life. Extension of the elbow for two or three weeks is the treatment for this. Fibrous union with a gap is nearly always satisfactorily treated by operation, but is infrequent.

Fracture of the coronoid process is treated by complete

flexion. Fracture of the head or neck of the radius is treated by full flexion. If obstruction to supination should occur, the fractured piece should be removed. Excess callus formation is prevented by not introducing any motion early. The author pleads for early reduction whenever possible.

Volkman's contracture, traumatic myositis ossificans, ulnar nerve or median nerve injury, and permanent restriction of movement from excessive callus formation in the fossae are the complications to look out for.

The operations indicated are not numerous and are as follows:

1. Removal of head of radius as mentioned.
2. Replacement of the epiphysis when it has been detached and turned turtle.
3. Excision of fractured fragments of the capitellum and trochlea.
4. Repair of co-existing nerve injury at the earliest possible movement.
5. Open reduction of any fracture not capable of being reduced otherwise.

A functionally good joint is the goal and not necessarily a pretty looking one.

There are a number of illustrations of several cases reported by the author.

V. C. HUNT.

DIVERTICULA OF THE URINARY BLADDER: W. E. Lower (Surg., Gyn. and Ob., August, 1923). Diverticula of the urinary bladder have become known as frequent occurrences only in recent years, through the advent of the cystoscope and cystographic examinations.

The etiology of diverticula is unsettled. Increased activity of the bladder musculature, secondary to some form of obstruction at the urinary outlet with a congenital predisposition to diverticula formation, seems to be generally accepted as the most likely etiological factor.

Diverticula present no specific symptoms. Their presence should be suspected, however, in any case in which difficulty of urination, frequency, and pyuria exist in concomitant conditions; also, wherever there is persistent pyuria, especially after repeated irrigations. Any abnormality of micturition should be an indication for a cystoscopic examination of the bladder, and this should include an anteroposterior plate and at least two plates taken from different angles.

An infected diverticulum can be cured only by complete removal. The author's method of procedure in good sized diverticula is, dissection of the diverticulum free from surrounding structures after it has been stuffed with gauze or cotton, followed by excision at the neck and closure by turning in the mucous membrane. A small diverticulum which can be readily everted into the bladder, can be removed intravesically. Any cause of obstruction should be appropriately treated. If a ureter opens into a diverticulum, as frequently happens, it should be transplanted.

Operation should not be delayed once the diagnosis has been made.

DIAGNOSIS OF CONGENITAL SYPHILIS IN INFANTS AND NEW-BORN: A. B. Marfan (*Presse Med.*, Paris, April 25, 1923). The diagnosis of congenital syphilis rests on the following clinical signs:

Pemphigus is relatively rare but generally exists at birth or within ten days after birth at the latest. It involves the palms and soles, and is to be distinguished from epidemic pemphigus, which spares these areas, and is never congenital. The presence of syphilitic pemphigus is of grave prognostic significance, few children so affected recovering.

Coryza is of prime importance, is an early sign and often the only one present. The only form of coryza which may offer diagnostic difficulties is diphtheritic rhinitis. Diphtheritic rhinitis is never congenital, and a bacteriologic examination usually settles the diagnosis.

Chronic early megalosplenitis is sometimes observed at birth and may, in connection with a variable degree of anemia, constitute the only symptom of syphilis. An appreciable enlargement of the spleen may be detected in about 77 per cent of heredo-syphilitic children under three months. Megalosplenitis up to this age has practically a pathognomonic value.

Syphilids are relatively rare. Macules similar to the roseola of acquired syphilis usually appear toward the end of the first month. They have two zones of predilection: on the face (lower lip, chin or neck), and on the external surface of the thighs. Syphilitic papules may develop from macules or appear independently. They occur a little later, and are almost never observed after the fourth month. Their usual sites are the face, lower limbs and ischiatic regions. Lesions similar to mucous patches may be observed in regions where two moist cutaneous surfaces are in contact with each other. Condylomas occur only in older children and are thought to be a manifestation of acquired syphilis. The syphilids of infants become ulcerated only in exceptional cases.

The syndrome of pseudoparalysis of new-born syphilitic children (Parrot's disease) generally occurs toward the sixth week, and almost never after four months. One or several limbs are inert, flaccid, and motionless. The limbs are not really paralyzed, but the movements are very painful. Sometimes a swelling may be felt in the region of the epiphysis, and even crepitus in the rare cases in which the diaphysis has become separated from the epiphysis.

The above signs are pathognomonic, but may all be lacking after about the sixth month. A diagnosis may still be made, however, from association of other signs, and by laboratory methods.

CHESTER A. STEWART.

BLEEDING FROM THE RECTUM IN INFANCY AND CHILDHOOD. Arthur A. Landsman (*Arch. of Ped.*, August, 1923). Rectal bleeding may arise from a variety of causes, local and general. There are many symptoms which may be borne for long periods, though quite annoying, without any particular danger to the individual, because they do not interfere with processes which are vital to life, or affect our reserve forces sufficiently to prevent function from being carried on. This is not true of loss of blood; steady bleeding, even in small amounts, is certain to be followed by such serious consequences as to make it necessary to check it without any loss of time. But if we are to secure more than temporary relief, the cause of the bleeding must be found. Any one of the disturbances which are held responsible for rectal bleeding in older children may be theoretically present in infants, but as a matter of practical experience there are only two which require any extended consideration in this connection—congenital syphilis and lesions which arise from developmental faults. In congenital syphilis the cause may be found in epithelial erosions, ulcerations, condylomata, fissures, cracks and other manifestations of lues, while those due to developmental defects owe their origin to some fault or modification in growth occurring in the lower end of the intestinal tube during prenatal life. While older children, who are brought to the proctologist for investigation of hemorrhage from the bowel, may also be the victims of diseases which affect those who are younger, yet in them, generally speaking, other conditions prevail which are sources of bleeding; these are polypi, prolapse of the rectum, invagination of the bowel, ulceration, fissure, foreign body and abscess. Prolapse of the rectum is relatively common in children up to 4 to 5 years of age and is accompanied by slight bleeding with or after stool.

Ulceration of the rectum is caused by a number of diseases, any one of which may give rise to symptoms of bleeding, varying from a few drops to a brisk hemorrhage. These are syphilis, tuberculosis, malignancy, amebiasis, the presence of intestinal parasites, gonorrhea and proctitis due to toxic causes. Gonorrheal ulcers occur most frequently in female children from a dribbling of the vaginal discharges in those who are so affected.

Fissures of the anal skin are seen in children of the undernourished type, who are suffering from constipation or diarrhea; they are not infrequently caused by straining or by the trauma inflicted by the careless use of the nozzle of the fountain syringe. Piles occur in infants and older children with extreme rarity, and are only mentioned here to emphasize this fact. Many cases diagnosed as piles, both in the child and in the adult, are really other forms of rectal diseases.

R. N. ANDREWS.

A COMPARISON OF THE VALUE OF MILK AND ORANGES AS SUPPLEMENTARY LUNCH FOR UNDERWEIGHT CHILDREN: Margaret S. Chaney (*Amer. Jour. of Dis. of Child.*, October 1923). One of the most common methods of overcoming undernutrition among school children is the introduction of a supplementary lunch, consisting usually of milk and crackers. Sherman and Hawley have recommended a diet containing a quart of milk a day and a normal allowance of other foods. This

will furnish a gram of calcium a day for the growing child, the amount which they have found necessary to induce optimum storage of calcium. However, it has been forcefully demonstrated by many investigators that all milk is not of equal food value since its vitamin content is altered by the fodder of the cow and also by the application of heat. Hess, while he advises the use of milk because of the security it provides against infection, states that it is an incomplete food, and a contributing cause of infantile scurvy.

Another point to be considered when milk is to be fed as a midmorning lunch is its satiating effect. In many instances, a glass of milk taken between meals or at the beginning of the meal will cause lack of appetite; and, as the undernourished child already has a tendency to diminish his food intake, this may be a more serious consideration than it appears on the surface.

Oranges also are a protective food and have an important place in the diet. Experimental work on the values of orange juice in infant feeding goes to prove that it is important not only as a source of the antiscorbutic vitamin, but also as a stimulant of appetite. Babies not gaining normally on the ordinary amount of orange juice (15 c.c., as fed by Daniels) receive a marked stimulation to growth when 45 c.c. is administered.

In ascertaining the state of well being of the child, environment and social standing as well as the physical conditions of the body are to be considered. The most common physical defects causing undergrowth and poor nutrition are caries and infected teeth, and enlarged and infected tonsils and adenoids. New Para oranges apparently are superior to milk as fed to the children involved in the test. The orange lunch instead of decreasing total food intake is likely to increase it, owing to the water-soluble vitamin in the orange.

Concentrated bottle orange juice appears to be of marked value in stimulating growth in the underweight child. While it has not proved equal to fresh oranges, it is quite effective, and may, if the fresh fruit is not available, supply the vitamins necessary for growth.

R. N. ANDREWS.

WHAT CURATIVE DIETS ARE NECESSARY FOR THE INFANT: Langstein (*Monatschr. f. Kinderhik*, Leipzig, January-February 1920). The poor quality of milk since the war has led to discontinuance of the one-third milk formula, which has been replaced by more concentrated mixtures. Langstein uses whole milk, half milk, two-thirds milk, breast milk and buttermilk. Breast milk is the best curative diet and cannot be replaced by albumin milk. For infants with acute diarrhea, breast milk, preferably, in combination with buttermilk gives best results. Buttermilk with addition of a little flour and sugar makes all other curative diets superfluous, even albumin milk, and is indispensable, even though many nutritional disorders may be treated successfully with ordinary milk formulas. Generally, curative diets are continued too long. It is unwise to give albumin milk for six to eight weeks, for disorders may develop which are often not immediately manifested clinically.

CHESTER A. STEWART.

RINGWORM AND ITS TREATMENT: James Robertson (*Arch. of Ped.*, August, 1923). The writer describes his method of treatment of ringworm which he has used in the School Clinics in Blackburn, England, since 1920. The hair is cut short; the affected parts are shaved; the areas are washed with ether soap and dried. Then the following lotion is carefully applied with gentle rubbing: Calomel, 5 grains; tincture iodine, B. P., one drachm. This lotion is poured on small pieces of absorbent cotton and applied to the areas; then a dressing is applied. The next day the dressings are removed and the areas washed with ether soap, ammoniated mercury ointment is applied and then a dressing and bandage. This is continued until the case is cured, which is usually within 14 days. The lotion is applied only once; it seems to penetrate and kill the parasites. If the whole scalp is affected then it is the custom to apply the lotion to one-sixth of the total area each day for six days. Ringworm of the body receives the same treatment, in which cases the condition is cured within 48 hours.

R. N. ANDREWS.

THE SIGNIFICANCE OF HEMATURIA IN CHILDREN: J. D. Leeborn (*Arch. of Ped.*, September 1923). This is not as common in children as it is in adults. Its occurrence is one of the most important manifestations of disease of the urinary tract in early life. There are two problems to solve in the presence of hematuria—the source, and the cause. It is very important to remember that a bleeding bladder is difficult to wash clear. Hematuria of renal origin is a total form. "It is always the result of a rupture of blood vessels which may be occasioned by many causes" (Jacobi). The urine shows a uniform discoloration from the beginning to the end of micturition. The three chief causes of renal hematuria are tuberculosis, stone and new growths. Certain mild vesical symptoms present themselves in incipient tuberculosis of the kidney. These are frequent urination, a slight, purulent deposit at the bottom of the vessel and mild pains in the bladder. In renal calculus, hematuria often appears abruptly without any previous attack of pain, while in other cases, pain is a prominent feature. Hematuria in new growths of the kidney may appear very early and may be the only symptom. In fact, sudden, profuse, painless hematuria should at once suggest nephritic neoplasm. Nephritis associated with hematuria, with or without pain, is of relatively frequent occurrence. Hematuria of hemic origin is a rather common occurrence in children. These are purpura, hemophilia, rickets, scurvy and the leukemias. Hematuria often follows certain forms of poisoning such as cantharides, phosphorus, turpentine, phenol and hexamethylenmin.

The treatment of hematuria depends largely upon the cause. The hemorrhage in itself is a symptom, rather than a disease. Rest and local application of cold, in the form of the ice bag, is indicated in all cases of profuse hematuria. The patient should be kept in bed and kept on a milk diet. The underlying principle of treatment is the removal of the cause of the condition. Palliative treatment is inexcusable except as it is temporarily resorted to during a careful search for the etiology.

GYNECOLOGY AND OBSTETRICS

SUPERVISORS:

ARCHIBALD L. McDONALD,

FIDELITY BLDG., DULUTH

ALBERT G. SCHULZE,

LOWRY BLDG., ST. PAUL

THE TREATMENT OF THE PREGNANT WOMAN WITH PULMONARY TUBERCULOSIS: M. Voron (*Gynecologie et Obstetrique Revue Mensuelle*, Tome 8, No. 2). The author gives an exhaustive review of the French literature on this subject, in which he presents the arguments and experience of the opposing schools, namely: those who recommend the routine interruption of pregnancy, and those who withhold all intervention. After a detailed discussion of the question involved and consideration of his own results he presents his conclusions as follows:

I. The treatment of the pregnant woman having pulmonary tuberculosis should be neither systematically conservative nor radical intervention, but each case must be treated according to circumstances and environment, independent of any preconceived ideas.

II. Treatment will be entirely medical:

1. When the pregnancy has passed three months independent of the nature and extent of the pulmonary lesions.

2. In cases of grave advanced tuberculosis, or in the quiescent or fibrous stage.

III. Interruption of the pregnancy may be considered when:

1. Pregnancy has not passed three months.

2. There is a tuberculous lesion definitely active, but is definitely curable in the opinion of competent observers. Intervention will be contra-indicated when the clinical and social conditions are such as to offer good hope of cure by medical treatment alone. Interruption of pregnancy will be limited then to patients presenting bilateral lesions still curable, usually in women of the working classes who are not more than three months pregnant. It is to be considered only in the exceptional cases, and the treatment will be medical and hygienic in the vast majority.

IV. When indicated, intervention will most often consist of induced abortion. Hysterectomy is reserved for women near the end of the childbearing period, who have borne several children, and who must be protected from further risk. Sterilization without hysterectomy has some advocates.

V. Physicians and obstetricians should realize that severe aggravation of tuberculosis is common during the puerperium. That medical and hygienic treatment should be instituted early in pregnancy and carried out rigidly throughout the puerperium. That intervention which is found to be favorable in some cases should always be considered during the early period at which it is permissible, namely, during the first three months of pregnancy.

ARCHIBALD L. McDONALD.

THE CALCIUM AND MAGNESIUM CONTENT OF THE BLOOD SERUM DURING PREGNANCY, LABOR, AND THE PUERPERIUM: E. R. Plass and L. Jean Bogert. (*Am. Jour. Ob. and Gyn.*, Vol. 6, No. 4.) This interesting piece of work was carried out in order to study the toxemias of pregnancy. They examined the calcium content of 205 normal, nonpregnant, pregnant, parturient, and puerperal women. Several observations were made on women suffering from toxemia of pregnancy. A number of analyses were made for magnesium but as no marked variations from normal were found, these were abandoned. The authors give an excellent review of the literature on this subject. They studied 40 normal nonpregnant women, 105 normal pregnant women between the fifth and fortieth weeks of pregnancy, 29 women during labor, and 31 from 12 hours to 12 weeks postpartum, for the serum calcium. The serum magnesium was determined in 16 normal nonpregnant women, 29 during pregnancy, 21 at the end of labor, and 18 postpartum. They outline their methods of work and results obtained in considerable detail, and discuss the significance of their findings. They conclude: There is a distinct tendency toward a lowering of the calcium per cent during pregnancy, especially during the latter part of this state. This is not found during the first eight weeks. They feel that these lower findings do not necessarily mean a calcium deficit in the mother, but may be explained on the basis of dilution of the serum (hydropasmia), for which there is considerable evidence. The values for serum calcium in the toxemias were not much lower than those found in normal pregnant women at the same stage of gestation. The magnesium content of the serum of nonpregnant women was quite constant. It showed a tendency to decrease during pregnancy especially at labor, but probably is to be explained by the same cause as serum calcium. They were unable to prove any relationship to toxemias. Both contents returned to normal soon after labor. The serum of pregnant women showed no significant variations in the calcium or magnesium content from that of normal nonpregnant women.

HEMORRHAGES IN THE NEWBORN: Lucius M. Wing (*Amer. Jour. of Ob. & Gyn.*, Vol. 6, No. 1). This article is of great importance to the obstetrician and is therefore reviewed in this column. The author comments on a statement that of 480 children suffering from cerebral spastic paralysis, with or without mental deficiency, intracranial hemorrhage at birth is responsible for 70 per cent of the spastic type of paralysis in children, and for 20 per cent of the idiocy and feeble-mindedness now existing. He emphasizes the fact that fatal intracranial hemorrhage may occur in a child born spontaneously in what is considered to be normal labor. More or less extensive intracranial hemorrhage is reported in from 30 to 50 per cent of the autopsies done on stillborn or newborn infants. In 59 fatal cases, 39 were vertex and 20 were breech deliveries. There was laceration of the tentorium cerebelli in 37 per cent of the total, and of these 63 per cent occurred in breech deliveries. Losee at the New York Lying-In

observed fatal intracranial hemorrhage twice as frequently in breech as in forceps deliveries. In vertex presentations, with normal engagement, and progress, the pressure effects are balanced and minimized by the support of the birth passage. More intracranial injury may occur in a few moments of unskillful forceps extraction, or forcible delivery of an aftercoming head, than from a long period of hard labor. The hemorrhage following extraction of the aftercoming head is usually in the more dangerous areas, namely beneath the tentorium or in the region of the medulla. Most of these babies are stillborn. Those which are resuscitated are likely to be limp, respiration is irregular, they become alternately pale or cyanotic, and are likely to die soon after delivery. Hemorrhage following vertex delivery is more often cortical and the prognosis is more favorable. Hemorrhage of some extent should be suspected in all babies showing asphyxia at birth, in whom resuscitation is difficult, or where the respiration is irregular. Small hemorrhages may be found in other areas: epicardium, liver, pleura, or retina. This type of baby should be regarded as a potential bleeder, and the author believes that asphyxia may have a causative influence on subsequent blood instability. Hemorrhages developing some hours or days after birth are usually associated with hemorrhagic diathesis, and are associated with bleeding in several regions: lungs, suprarenals, etc. At the Lying-In Hospital the subcutaneous injection of human serum has proven valuable if given early. 100 c.c. is given in three or four doses in the first twenty-four hours. Whole blood gives much the same result, is simpler, but may cause more local reaction.

ARCHIBALD L. McDONALD.

CYSTOCELE AND HIGH RECTOCELE: Thomas J. Watkins. (*Am. Jour. Ob. and Gyn.*, Vol. 6, No. 4.) Concerning cystocele, the author accepts as proven the following statements: (1) Cystocele is a hernia of the bladder. (2) That the lesion is essentially a tear in the vesico-vaginal floor. (3) That operative treatment must include a thorough dissection of the hernia, a firm closure of the hernial ring, and thereby, a restoration of the bladder and urethra to their normal positions. The laceration in the vesico-vaginal floor is transverse, and not longitudinal, which explains the urethral displacement. The excellent illustrations demonstrate the author's conception of the pathology and the operative procedures which he recommends for the successful correction of the condition.

Watkins' dissections of high rectoceles have convinced him that in these cases the injury consists of a tearing of the supporting fascia from the cervix and broad ligaments in a manner similar to that which obtains in cystocele. He states that the edges of the hernial ring can be dissected free and finally fastened to the cervix without undue tension. This is well shown in his illustrations, as is also the preferable method of closure. In addition, or in simpler cases alone, we may have the perineal lacerations in which the muscles are lacerated or torn from their attachments to the rami of the pubes. The article is well worthy of careful study.

ELEVATION OF THE DIAPHRAGM. UNILATERAL PHRENIC PARALYSIS. A RADIOLOGICAL STUDY WITH SPECIAL REFERENCE TO THE DIFFERENTIAL DIAGNOSIS: J. M. Woodburn Morison (*Arch. of Radiology and Electrotherapy*, Vol. 27, p. 353, May 1923; Vol. 28, pp. 71 and 111, August and September 1923). This series of well-illustrated articles represents a thorough anatomical and radiological study of the subject with report of a large number of cases. Petit's "Eventratio Diaphragmatica" and unilateral phrenic paralysis are considered together as they are practically indistinguishable clinically or radiologically. The author believes the former to be due to a developmental defect in the formation of the muscular tissue of the diaphragm. The latter are acquired and are usually due to pressure from a new growth on the phrenic nerve.

In the radiological examination, the important points to be considered are:

1. The bow line in the chest, unbroken, dome-like, the relaxed diaphragm.
2. The contents of this dome, stomach or both stomach and colon.
3. Lung tissue seen through the dome, depending on whether or not there is a hypoplasia or a consolidation of the lung.
4. Reversed movements of the bow line, upward with inspiration.
5. Fluid level of the stomach contents.
6. Palpation of the abdomen produces waves in fluid level of stomach.
7. Heart shadow seen through the dome, rotated to the right.
8. Chest wall development normal with decrease in the movements of the lower ribs and at the apex on the affected side.
9. There may be marked deformity of stomach with two sacs, rotation, or even volvulus. Gastric symptoms may thus occur. The cardinal signs are the bow line in the chest with reversed movement on inspiration.

Temporary elevations must be differentiated. Under the screen these show normal movements of the diaphragm, there is no paralysis, and they disappear in a few days. Diaphragmatic hernia is distinguished by the break in the diaphragm, with prolapse of the viscera into the chest. There is no bow line, no movements, and the position of the viscera is seen after giving an opaque meal. Localized hydro-pneumothorax, subphrenic or subhepatic abscess are easily distinguished by the opaque meal when on the left, and by the position of the liver if on the right.

LEO G. RIGLER.

OSTEOCHONDRITIS DEFORMANS JUVENILIS: Kirklin (Am. Jour. Roent., September 1923). This disease, first described by Legg in 1909, later by Calve and still later by Perthes, is usually known by the latter's name. Most of the cases reported were first diagnosed tuberculosis of the hip, as were the cases seen by the author. Its occurrence in children, often following injury, and its insidious onset resemble tuberculosis. The chief symptom is a slight limp, increasing in degree, but recovery usually occurs without much loss of function. Ankylosis does not occur. According to the author, the roentgenograms are so characteristic that the diagnosis can be made by this means alone. Frequently this is the only means of differentiating the disease from tuberculosis. The epiphysis of the femur is flattened out and the neck is broadened. This process continues until the head is a thin disc composed of several segments which may later fuse. The neck becomes broader, eburnated, and may simulate a coxa vara in appearance. The acetabulum may show osseous changes, some of which are thought to be part of the same process which is going on in the epiphysis, and some are thought to be due to the pressure changes in the joint.

THE EFFECTS OF INANITION IN THE PREGNANT ALBINO RAT. By L. W. Barry, M.D., St. Paul, Minn.

Published in the Carnegie Publications, Contributions to Embryology, No. 53.

This monograph represents the findings of an extensive research on the effects of inanition on the pregnant mother and her offspring. The work has involved the study of sufficient adequately controlled material to make the conclusions significant. "The main object of this investigation, therefore, is to show the effect of inanition in the pregnant albino rat upon the changes in the relative weights of the various systems, organs, and parts of the new-born. Observations were made also on the possibility of blighting of the ovum, death of the fetus in utero, prolongation of gestation, abortions, and premature deliveries during inanition of the mother."

"Starvation instituted shortly after copulation in the female albino rat apparently results in an inhibition of pregnancy in the majority of cases. Whether this is due to an inhibition of the implantation, or to death of the ovum, has not been proved."

Starvation during the last half of pregnancy prolonged the average period slightly.

"No abortions or premature deliveries were observed in any of the underfed rats."

One-third of the newborn from mothers starved in the last half of pregnancy were either born dead or died immediately after birth.

There is a slight diminution in average number of young per litter from mothers starved in the last half of pregnancy.

"A condition of relative sterility apparently results in females starved in the last half of pregnancy."

The average weight of the newborn from mothers starved severely during the last half of pregnancy was approximately 40% below the normal birth weight.

In regard to the detailed observations on the changes noted in the case of the various organs and systems it is interesting to note that the chief loss of weight was at the expense of the liver and lungs. The central nervous system (brain and spinal cord) was very little affected.

E. H. NORRIS.

FOR SALE—Southern Minnesota village practice. Scandinavian preferred. Examiner for several Life and Casualty Insurance Companies. Yearly income over \$6,000.00 cash. Price \$500.00 for practice and equipment. Leaving soon to do special work. Address B76, care of MINNESOTA MEDICINE.

WANTED—German Catholic physician, town of 400. Good farming community. Nearest doctor 10 miles. 25 miles from St. Paul. Other villages nearby without physician. Office and residence for rent. Nothing to buy. Address P. O. Box 233, Hampton, Minn.

WANTED—Position as laboratory and x-ray technician or as doctors' assistant by experienced young woman. Address B77, care MINNESOTA MEDICINE.

\$12,000 MISSOURI PRACTICE FREE—Wonderful location. General practice. 95% collections. Good opening for small hospital. Overwork cause of sacrificing proposition. Buy office effects and take practice. Address B80, care MINNESOTA MEDICINE.

PHYSICIANS' OFFICES FOR RENT. Choice of 7 rooms in good location. Splendid reception room, nurse, stenographer, bookkeeper in attendance. Address B78, care MINNESOTA MEDICINE.

CUTANEOUS TUBERCULOSIS AND TUBERCULIDS IN DIAGNOSIS*

JOHN H. STOKES, M.D.

Chief of Section on Dermatology and Syphilology
Mayo Clinic, Rochester, Minnesota

In the time allotted me it is of course impossible to review for you, all the varied reflections of tuberculosis in the mirror of the skin. So extensive a structure as the skin, so large an organ, one might say, with its enormous capillary circulation acting as a strainer for both organisms and toxins, must, in spite of its relative stability and resistance to internal and external attack, frequently register the onset and course of tuberculous infection. The extraordinarily wide range and clinical variety of these lesions have received monographic consideration in the writings of such observers as Jadassohn, Brocq and others, but in American literature has a comparatively restricted notice. Part of this lack of attention is, I believe, the result of general unfamiliarity with dermatology on the part of even our most alert diagnosticians. A wider acquaintance would soon extend the field of our first-hand knowledge of tuberculosis as it affects the skin, and would increase our appreciation of its value as an aid in the diagnosis of systemic disease. With this idea in mind I take this opportunity to call to your attention four aspects of cutaneous medicine in which tuberculosis plays a leading part, and to emphasize particularly the diagnostic earmarks by which the general practitioner, no less than the expert, may have his suspicions aroused and be led to fuller study and observation and to eventual accurate diagnosis.

THE APPLE-JELLY NODULE AS AN EARMARK IN CUTANEOUS TUBERCULOSIS

The accessibility of the skin to visual examination makes it possible to do in life what unfortu-

nately is denied us in tuberculosis of deeper structures, to see the tubercle in situ, by the very simple device of expressing the blood supply from the inflamed surrounding tissue by glass pressure. While tubercles do not differentiate sharply in certain types of cutaneous tuberculosis, in others are too deeply situated for observation, and in still others are usually prevented from forming by the violent destruction of tissue and organisms in an allergic

Fig. 1 (Case A187333). Early lupus vulgaris of the tip of the nose. Apple jelly-nodules demonstrable on pressure by glass slide. The preliminary diagnosis was "frost bite." Local and general reaction to tuberculin.

local tissue reaction, the cutaneous tubercle is common enough in processes such as lupus vulgaris, of the ulcerative type, in the dry lupus vulgaris erythematoides, and in certain forms of inoculation tuberculosis, to make its identification helpful in differentiating the tuberculoma from other granulomas and non-granulomatous processes.

*Read in symposium before the Minnesota State Medical Association, October 10-12, 1923, St. Paul.

The cutaneous tubercle or apple-jelly nodule is a small translucent brownish or apply-jelly colored infiltration, rarely more than 2 or 3 mm. in diameter, entirely invisible against its inflammatory background until the blood has been expressed from the surrounding tissue by pressure from some transparent object (Fig. 1). A glass slide, a glass tongue depressor or pleximeter, or an unmounted biconvex lens may be used. Even a glass paper-weight or the side of a tumbler may be utilized for emergency observation. The glass object must be stout enough to permit of a fairly firm pressure without breaking, or a severe cut may be inflicted. In a lesion which is markedly scaly or crusted, the surface should be carefully cleaned of detritus, so that no confusion from surface matter may occur. The tubercle is in the skin, not on it, almost perfectly round, flattened somewhat by the pressure, and rarely solitary. A group or chain is common, and a lesion in which only a single nodule occurs cannot thereby be proved tuberculous. Not infrequently in cases in which the local reaction to the infection is slight, as in dry lupus vulgaris, the fawn brown of the gross lesion first arouses suspicion, and when on pressure this color persists in spite of the pallor, and discrete small brownish nodules can be made out, tuberculosis is a strong presumption.

Of the conditions in which one would be likely to use this differential criterion, epithelioma and syphilis are most likely to simulate tuberculosis. Epitheliomatous cell nests are typically pearly nodules, not brown. They are usually confined to the border, rarely persisting in the scar as do tubercles. A definite telangiectasia can usually be recognized, which is not found in the avascular tubercle. The epitheliomatous "pearl" is harder, does not flatten so well under glass pressure, and shows more elevation above the surface of the skin, than a tubercle.

In late syphilids, especially about the face, the differential problem is often serious. Nicolas pointed out that the tuberculous apple-jelly nodule might be simulated by miliary gumma, and be present in syphilids of the skin which clinically resembled tuberculosis. In my experience, it is rare to see miliary gummas in considerable numbers as small as the average apple-jelly nodule. Larger nodules approaching 5 to 7 mm. are the rule. But even this criterion may fail in cases in

which nests of agminated tubercles have developed. The resemblance of a late syphilid of the face or nose to the dry erythematous, hypertrophic or even ulcerative type of lupus vulgaris may be so marked that pathologic differentiation by biopsy, by tuberculin subcutaneously, and by a therapeutic test must be resorted to in the effort to reach a diagnosis. In using the therapeutic test it is important to recall that arsphenamin has marked, though usually temporary, non-specific effects in cutaneous tuberculosis, and that even mercury intramuscularly may produce some clearing in a tuberculous lesion of this type.

In general, then, it is well worth while from the standpoint of general diagnosis, to apply glass pressure to the borders of indurated persistent plaques, small ulcerations, cutaneous nodules, and the

Fig. 2 (Case A256104). Lupus vulgaris erythematoides, the dry extensive non-ulcerative tuberculosis of the skin. Note the miliary tubercles in the border, two or three of them ulcerative, also the tubercles in the thin dry atrophic scar. They are easily demonstrable on glass pressure.

periphery of larger persistent patches of what may have been thought at first sight to be dry eczema, psoriasis and benign inflammatory conditions. A border of apple-jelly nodules, and the persistence of similar nodules in a dry atrophic scar (Fig. 2) may often lead to the diagnosis of a local tuberculous lesion in time to prevent metastasis or extensive destruction. A careful constitutional search

may reveal a deep focus of the greatest importance to the patient's welfare.

LICHEN SCROFULOSORUM, THE TOXITUBERCULID

The term "toxituberculid" is being attacked from all sides, the contention being that cutaneous lesions heretofore regarded as simply concomitants of tuberculosis elsewhere in the body are gradually being shown by combined clinical and experimental

Fig. 3 (Case A319031). Lichen scrofulosorum on the flank in a young child. The patient came for a cleft palate operation and following a recognition of the lichen scrofulosorum, an examination for tuberculosis disclosed an extensive active infection with pulmonary manifestations.

study to be actual tuberculosis, caused by the organisms themselves and not by the effect of toxins from a remote focus. One type of lesion, however, seems thus far to have survived the effort to do away with the conception of toxituberculids, and that is the grouped follicular papular eruption known as lichen scrofulosorum which apparently can be produced experimentally by rubbing in tuberculin. This eruption has been regarded as a rarity in this country, though apparently common in Europe. Some of this rarity, however, may be the result of unfamiliarity.

In the clinical identification of lichen scrofulosorum, every one of the words used in the above designation of its characteristics is important. The eruption is grouped, not uniform or evenly distributed. Ten to fifty or a hundred papules are assembled into each close-set patch, and two or three up to fifty or more groups may be present (Fig. 3). The elementary lesion is follicular in character. The morphology of the follicular papule varies a good deal, especially in adults. It may be simply a follicular accentuation, the

patch resembling an island of permanent goose-flesh. There may be horny plugging of the follicle mouths (Fig. 4) though this characteristic brings it perilously close in diagnosis to the confusing elements of lichen spinulosus, follicular lichen planus, lichen pilaris and keratosis follicularis. The follicular papule is practically non-inflammatory and of a flesh or yellowish tint, which helps to distinguish it from perifollicular seborrheic dermatitis, the follicular syphilid and keratosis pilaris and follicularis. Slight hyperpigmentation of the patch of skin affected is the rule, the pigmentation being definitely less than that usually associated with the follicular syphilid. The groups or patches are usually relatively few in number, occur on the flank or in odd places on the upper extremities, and are rarely so abundant, small and widely distributed as are the groups of the follicular secondary syphilid.

Fig. 4 (Case A426165). Lichen scrofulosorum on the flank in a boy with what was at first thought to be the type of symmetrical hydrarthrosis of the knees, often seen in heredosyphilis. The identification of the cutaneous lesion led to a search which demonstrated the tuberculous origin of the process.

A follicular eruption presenting characteristics quite similar to those of lichen scrofulosorum has been recognized in recent years, and is of importance in differential diagnosis. This is the toxi-

trichophytid (Fig. 5) associated with a focus of trichophytic or ringworm infection, and especially with the macaroon-like crusted trichophytic granuloma known as kerion celsi. It is a grouped follicular eruption with a distribution and appearance suggestive of some cases of lichen scrofulosorum, but the ringworm lesion from which the intoxication is proceeding is usually easily identifiable. I have, however, seen it overlooked in the form of a patch of favus on the scalp, with favus of the nails. As in the case shown, it may consist merely of a superficial scaling trichophyte of the leg.

Lichen scrofulosorum has the reputation of being more common in children than in adults, but my experience has been the reverse of this. The lesion is apt to be more conspicuous in children, and therefore perhaps more often identified. I have observed it in association with pulmonary tuberculosis, and especially with tuberculous arthropathies, practically never with tuberculous glands, which are much more frequently accompanied by the papulo-necrotic tuberculid. A good light, a habit of critical inspection of the skin, ability to identify a follicular lesion, and some familiarity with the range of follicular lesion differentiation involved is essential. In city practice and on hospital staffs where dermatologic consultation is available, it often proves a valuable confirmatory aid in diagnosis, and may even, especially in children, set in motion an investigation which discovers an unexpected tuberculous focus.

DISSEMINATE ERYTHEMATOUS LUPUS, THE TUBERCULO-SEPTIC ERYTHEMA MULTIFORME

Lupus erythematosus is an unfortunate name, especially so because the term "lupus" leads the majority of physicians to associate the process with a true tuberculosis of the skin. To make a diagnosis of "lupus" is essentially meaningless, unless one specifies what "lupus" is meant. If one means cutaneous tuberculosis of a certain type he should say "lupus vulgaris"; otherwise he may find that he is confusing the condition with what is now regarded as in many cases a type of erythema multiforme, namely lupus erythematosus.

Lupus erythematosus presents two clinical types, the chronic discoid or localized form, and the disseminate type with systemic manifestations. The chronic type does not seem to be associated with tuberculosis in clinically recognizable form in more than about 30 per cent of cases, and for that

reason is not referred to here. The essential lesion of the chronic discoid type is a follicular inflammation with atrophy. The localization about the nose and face, forming the textbook butterfly pat-

Fig. 5 (Case A423734). The lichenoid trichophytid in a patient with a ringworm on the leg. This eruption may be confused with lichen scrofulosorum, but the trichophytic focus can always be found. Note the grouped follicular character of the eruption.

tern, is familiar to all. The frequent involvement of the scalp, producing patches of complete baldness from destruction of the hair follicles, is less familiar, and the common involvement of the outer anterior surface of the concha of the ear is also often overlooked. Acute disseminate erythematous lupus may supervene on a chronic erythematous lupus of many years' duration, or it may appear in obscure or full-blown form from nowhere. Whenever what seems to be a chronic erythematous lupus can be identified on the face, or on the scalp, and purplish patches can also be found on the fingers or backs of the hands, or when the process on the face is extending downward onto the neck and arms, a menacing situation has arisen, and dissemination may be regarded as a possibility. The situation is menacing because while discoid lupus

erythematosus is usually merely disfiguring, disseminate erythematous lupus is a highly fatal disease, with constitutional accompaniments that range all the way from imitations of typhoid fever, malaria, trichiniasis, acute rheumatic fever, and acute abdominal accidents, to cutaneous pictures suggesting erysipelas, exfoliative dermatitis and pellagra¹ (Fig. 6). In fact, repeated attacks of high fever in patients of low vitality, accompanied by any erythematous eruption (especially on the face), soreness of the mouth, falling of the hair (Fig. 7), arthritic symptoms, nephritis, or vague abdominal complaints, should prompt the most careful inves-

the tuberculous element in disseminate erythematous lupus, and its relation to the septic factor. Lymphatic tuberculosis, 'often of the mesenteric glands, and not recognized at times until necropsy, has figured prominently in our cases. The cross-fire of a tuberculous and a septic hypersusceptibility seems to underlie the peculiar clinical picture.

THE PAPULONECROTIC TUBERCULID

Lesions of the type of the papulonecrotic tuberculid, with its near relative, erythema induratum, are in my experience most valuable aids in general medical diagnosis, especially of glandular conditions; in the determination of the effectiveness of surgical procedure for the extirpation of a tuberculous focus, especially in glands; in the detection of a tuberculous factor in eye conditions and in the unravelling of obscure ill-health and asthenia in women. While the eruptive lesions themselves are frequently the occasion for the patient consulting the physician, they may, as in the papulonecrotic tuberculid of the face (acnitis), or that of the

Fig. 6 (Case A416047). Disseminate erythematous lupus simulating erysipelas and pellagra. The persistent edema and erythema of the face with alopecia with extension of the process onto the neck and the appearance of erythematous lesions on the hands is part of the cutaneous picture of the disseminating type of this disease.

tigation for disseminate erythematous lupus. This is especially important because death may follow promptly, either on the attempt to use tuberculin in diagnosis, or to remove a focus of infection in tonsils or teeth, or to explore surgically for some of the vague abdominal symptoms. The ultimate outlook is always grave, even with the best of management.

It is impossible in the time available to discuss

Fig. 7 (Case A364069). The alopecia of disseminate erythematous lupus which should not be confused with that of syphilis. This patient also had lesions in the mouth and on the hands suggesting pellagra. He died in a typical hyperpyrexial attack.

hands (folliclis) (Fig. 8), be disregarded as merely trifling annoyances and disfigurements, while the patient seeks relief for arthralgia, tenosynovitis, persistent anemia, amenorrhea, symptoms of pelvic

Fig. 8 (Case A228772). Papulonecrotic tuberculid on the fingers (folliclis). Note the papules with their central necrotic plugs and pits. The scars are quite characteristic. The lesions tend to localize at points of trauma. Over 90 per cent of papulonecrotic tuberculids occur on the extremities.

peritonitis and salpingitis, uveitis, retinal hemorrhages and vitreous opacities, supposed Hodgkin's disease, psoas abscess, "neurosis," or an occasional partial positive Wassermann reaction, with its accompanying diagnosis of syphilis.

To the best of our present knowledge, the appearance of the lesion known as a papulonecrotic tuberculid, means a tubercle bacilleamia, controlled by a hyperallergy on the part of the patient, which leads usually to the destruction of the organisms that reach the skin. This destruction is accomplished by a local inflammatory reaction which appears clinically as an inflammatory papule with a central necrosis. In those cases in which the tuberculosis bacilli are not entirely destroyed, tubercles and organisms may be found in the reacting tissue, especially in the condition known as erythema induratum.

It should be said at the outset that a septic, non-tuberculous factor is involved in the production of tuberculids and that the removal of such a septic focus may cause temporary or permanent improvement. One is therefore led at times to the belief that the true tuberculid may be closely imitated by what might be called a "septid."

The close generic relation of tuberculids to erythema multiforme becomes very apparent on extended study, and any considerable clinical experience will furnish instances in which a transition from one to the other occurs, or in which erythema multiforme (Fig. 9), purpura and erythema nodosum serve as the prodromal indications of a tuberculous infection, or of the miliary dissemination of the organism with a fatal issue.

In the diagnosis of papulonecrotic tuberculids it is important to learn to identify the elementary lesion. Here again the name exactly describes it, at least in its maturity. At the outset, it is usually a hemorrhagic deep vesicle or an inflammatory nodule. On the hands and fingers, the vesicular phase is best seen; on the lower extremities and face, the nodular. The papular infiltration presently develops a central necrosis, which dries into a hard, brown to blackish plug, that can be dug out, leaving a superficial ulcer or a crateriform excavation (Fig. 8). During the development of this lesion the patient complains of tenderness on pressure which, if the lesion be on the finger, gives a sensation as of a thorn or splinter pressed into the flesh. In "stasis legs" and open lesions about

Fig. 9 (Case A217298). The clinical transition from erythema multiforme to a papulonecrotic tuberculid. This patient had a tuberculous salpingitis with erythema multiforme of the backs of the hands and folliclis lesions of the tips of the fingers. Note the folliclis scars on the right index finger.

the ankles the tenderness may be exquisite. In the normal course of events, the smaller papulonecrotic lesions heal slowly, leaving depressed atrophic scars, often round and varioliform, with a faint ring of hyperpigmentation. The absence of grouping in these scars is an important aid in differentiation from syphilis.

The appearance of papular lesions in clumps may result in coalescence on the lower extremities, or large boggy plaques with central breakdown (Fig. 10) and a grumous discharge may appear without isolated papules, forming the clinical picture of erythema induratum of Bazin. The occurrence of a reddish tender plaque, or even several nodes in the calf or posterior surface of the lower leg of a young woman inclined to overweight, carries a strong presumptive diagnosis of erythema induratum and should lead to painstaking search for tuberculosis.

Tuberculids show an overwhelming tendency to localize to the dependent portions of the body, and are most often found on the arms, hands or legs. The blue, cold hand or foot ("vasomotor foot") is a common accompaniment, or perhaps better, predecessor of a tuberculid, and a careful search of blue and mottled fingers or feet often reveals the scars of lesions. Association with glandular tuberculosis in more than two-thirds of the cases, and a marked seasonal onset, with exacerbations in spring and fall, are important points. All patients with tuberculids should be searched for glandular

tuberculous foci. Roentgen rays of the chest are important. Conversely all patients presenting evidence of glandular enlargements should be searched for signs of a tuberculid. There is often no better

Fig. 11 (Case A234128). Characteristic scarring of the extensor surface of the forearms and elbows by a papulonecrotic tuberculid. Note the varioliform punctate depressed scars and the lack of any configuration which would suggest a syphilid. Note also a few active lesions with central plugs.

Fig. 10 (Case A218528). Papulonecrotic tuberculid with erythema induratum of the legs. The livid infiltrated plaque on the posterior surface is erythema induratum. These plaques often undergo ulceration. Young women who are overweight and have a tuberculous focus are predisposed to this condition. It may be closely simulated by an eruption of septic origin and should not be confused with varicose ulcer.

clinical check on a premature diagnosis of Hodgkin's disease or lymphosarcoma, than dermatologic consultation on small pimples, spots, and scars on face, fingers, and legs.

The sites which should receive special attention in a search for tuberculids are the fingers, especially those which are exposed to trauma, on which we may find the classical papulonecrotic lesions of so-called folliclis. The extensor surfaces of the forearms and elbows (Fig. 11) are often the site of typical symmetrical varioliform scarring and an occasional active lesion. Papulonecrotic lesions on the face should not be lightly dismissed as acne, which is nodular or pustular and accompanied by seborrhea and comedones, but seldom presents the necrotic plugged centers of the typical tuberculid (Fig. 12). An important point is the involvement of the external ear in papulonecrotic tuberculids (Fig. 12), giving rise in chronic cases to a shrink-

age and scarring of the lobe which I have described as "moth-eaten ear." Tuberculids about the face seem to be specially inclined to come in showers, and a shower of lesions may produce a picture ranging in differential possibilities from acne to

Fig. 12 (Case A257865). Acnitis, the papulonecrotic tuberculid of the face which is often confused with acne and the papular secondary syphilid. Note the occurrence of typical papulonecrotic lesions on the lobe and concha of the ear. The recurrence of these lesions produces the ragged or moth-eaten ear which is of assistance in diagnosis. Papulonecrotic tuberculids are associated in more than two-thirds of the cases with glandular tuberculosis. The response of these lesions to arsphenamin increases the possibility of confusion with syphilis.

variola and papular syphilis. Care should be taken not to regard the papulonecrotic lesions of acne necrotica, which are usually most abundant along the hair margin and in the scalp, as a tuberculid.

Confusion with syphilis is one of the commonest diagnostic errors arising in connection with papulonecrotic tuberculids. The undoubted occurrence with certain Wassermann technics of partial or even complete false positives on the blood in persons with tuberculids is important. The constitutional symptoms accompanying tuberculids, especially arthritic pains with anemia, seem also to lead to frequent confusion. The morphologic resemblance

of a severe crop of acnitis (tuberculid of the face) to a papular syphilid is undoubtedly great (Fig. 12), and the scars of repeated attacks of erythema induratum with breakdown and ulceration may resemble those of a syphilid more closely than any other dermatologic lesion (Fig. 13). The response of tuberculids to arsphenamin (though they are resistant to mercury), the tonic non-specific effects of the drug in certain tuberculous patients, and its influence on tuberculous eye conditions, still further increase the possibilities of confusion. In therapeutic tests, arsphenamin must not be used. I have seen great social injury and discrimination, even divorce (Fig. 14), to say nothing of needless surgical interventions and medical misinterpretations, result from the deceptive influence of these various possibilities of error.

I would not have you feel that so cursory a review can cover the possibilities and fascinations of the tuberculosis and paratuberculosis of the skin. I have merely touched the surface of the subject in the hope that an occasional diagnostic "coup" which you may score by even a limited familiarity

Fig. 13 (Case A358132). The scarring of a tuberculid on the posterior aspects of the legs. Note the arciform scars with hyperpigmented borders suggesting those of a syphilid. There are, however, many individual scattered varioliform scars.

Fig. 14 (Case A171947). Papulonecrotic tuberculid of the feet and legs with the ulcers of erythema induratum. Note the scars of unnecessary surgical excisions and the resemblance of the normal scarring to that of a syphilid. This patient's husband endeavored to make her response to arsphenamin a cause for divorce on the ground that she had been treated for syphilis. Patients with tuberculids and no evidence of syphilis may occasionally give nonspecific partial positive blood Wassermann reactions.

with this most interesting group of dermatoses, may lead you to look further. I hope it will convince you, too, in the doing of it, that the dermatologist at his best should be not merely a mouther of hard names, with a specialty only half a centimeter deep, but an internist, whose major interest is that re-

markably efficient and highly complex organ or rather group of organs, the skin.

ARGUMENTS AGAINST THE CONTINUANCE OF THE WAR TAX UNDER THE HARRISON NARCOTIC ACT

In protesting against the continuance of taxation under the Harrison Narcotic Act at the rate fixed by the Revenue Act of 1918 as a war measure, three dollars a year, it should be made clear that the medical profession is not protesting against the Harrison Narcotic Act itself, nor against such taxation under it as may be necessary to give the federal government jurisdiction. The Harrison Narcotic Act originally fixed a tax of one dollar a year, which was deemed sufficient to secure federal jurisdiction, and of that tax no complaint was ever made. Any tax in excess of the minimum amount necessary to give federal jurisdiction is essentially an occupation tax on the physician and as such represents a discrimination against the medical pro-

fession, since federal occupation taxes are not imposed on other professions. So far as this tax may be passed on by physicians to their patients, it is a tax on the sick and injured, falling on them because they are sick and injured. The tax collected under the Harrison Narcotic Act is paid into the general revenues of the United States, and does not go directly toward the enforcement of the act. The amount collected under this act from all sources is largely in excess of the amount expended for the enforcement of the act—in 1922, for instance, \$610,311.13 in excess of the amount expended during the same year. In any event, however, there is no reason for imposing on the medical profession any greater part of the cost for enforcing the law than is imposed on any other group in the community, for the law is enacted for the benefit of the community and not for the benefit of the medical profession.

TUBERCULOUS DISEASE OF BONES AND JOINTS.*

CARL C. CHATTERTON, M.D., F.A.C.S.

Associate Professor of Orthopedic Surgery,
University of Minnesota

St. Paul

The better understanding of tuberculous disease of bones and joints has well kept pace with our knowledge of tuberculosis as found elsewhere in the human body. The past decade has brought new aids not only in the pathology, diagnosis, and differential diagnosis, but especially in the wider dissemination of knowledge of treatment. Surgical principles brought forward by the late war have in a great measure in my opinion advanced especially the best conceptions of bone and joint surgical procedures both mechanical and operative.

We are universally agreed that tuberculous disease of a bone or joint is a secondary infection from some other source in the human anatomy, and that the tubercle is carried to the bone and joint structures by the blood stream. Most authorities agree that the tubercle begins its process of destruction only where blood vessels may lead, and may involve bone shaft, epiphysis or cartilage, and only secondarily from breaking down of some of these is the synovia of a joint involved. Pure synovial tuberculosis does not exist, as outside destruction must occur before synovia becomes infected.

The old question as to whether the infection in a bone or joint is of human type or bovine type is still unsettled. From observations of the various reactions in children and adults, I am of the opinion that in my experience children respond more frequently to the bovine reactions while in adults the reverse is true.

The tubercle bacillus when it becomes located in bone or cartilage destroys it, forming a granulation tissue of low vitality, but always with a slight tendency to heal by calcification, encapsulation or cicatrization.

It is well to remember the pathology of healing of a tuberculous focus in bones and joints because the principles of treatment, rest and protection, can only aid the primary tendencies of calcification, encapsulation and cicatrization. Tuberculous disease then in bones and joints is arrested depending

upon the strength of the primary tendencies, and the principles of methods now in vogue in treatment of these conditions are outside aids that tend to strengthen the already pathologic tendency.

Laboratory aids in the diagnosis of tuberculous conditions are many. The roentgen-ray findings are all-important not only as a diagnostic aid in bone and joint disease, but also in detecting evidence of tuberculous disease in other parts of the body, especially the lung and mediastinum. *Von Pirquet* reactions (bovine and human), we commonly find positive in apparently healthy children over four years of age, while children with gross and severe tuberculous lesions often fail to respond. *Manteau* intradermal reactions seem slightly more constant and of more value than the extradermal of *Von Pirquet*. *Wildbolz* autogenous urinary reaction (urine concentrated to one-tenth normal volume and injected intracutaneously) with absent nephritis and staphylococcemia has according to some authors been quite positive in cases of known tuberculosis. *D'Espine* sign in the diagnosis of bronchial gland tuberculosis in our experience has also been positive in a great number of children suffering with joint tuberculosis (again emphasizing secondary infection of bone). *Complement fixation* tests, according to various authors, in children over six years of age compare about the same as adults, about 80 per cent giving fixation reaction.

Tuberculosis seems prone to affect the weight bearing joints. The spine because of its multiple segments seems most frequent, hip and knee follow closely, the ankle and small bones of the foot being more frequently involved than the shoulder, elbow, wrist and digits. The shafts of bones are perhaps involved more frequently than we believed in the past, presenting usually a low grade infection with bone destruction, great proliferation of granulation tissue and sequestra of bone-sand variety.

It is impossible in a short symposium to describe in any detail various areas affected, and only brief general statements may be made. Certain characteristics, however, are noted in tuberculous bone and joint conditions that are well worth notice. Onset of tuberculosis, bone or joint, is an insidious, slow, gradual one, and slight pain gradually progressing is the absolute rule. Muscle spasm is present early, and as a result of muscle

*Presented in symposium before the annual meeting of the Minnesota State Medical Association, St. Paul, October, 1923.

spasm atrophy comes early and is a constant sign in joint lesions. Slight deformity may be present early, but marked degrees depend somewhat upon the character of the part affected and the progress of destruction in bone, cartilage and surrounding tissue.

The principles of treatment of tuberculous joints are rest and protection and prevention of deformity. These measures are obtained through mechanical apparatus, surgical procedure, good hygiene and heliotherapy.

Pott's Disease.—In children absolute rest can be obtained by means of a Bradford gas-pipe frame; marked deformity is rare and deformity is improved when this apparatus is used until definite arrest is obtained. The ankylosing operations of Hibbs and Albee are of value in children over ten years and especially so in high dorsal and lower lumbar locations of the spine. In my opinion, in the future the ankylosing operations are going to be rarely used. Taylor braces, Calot plaster jackets, leather and celluloid corsets, are still used with absolute success in treatment of Pott's disease.

Hip Joint Disease.—Prevention of deformity is all-important. In children the Jones abduction splint with extension is extremely satisfactory. Ambulatory apparatus is quite essential in the older cases and is desirable in quiet cases in children. Surgical procedures to aid early ankylosis in the hip joint, especially in adults, are being advised by some authors. Sub-trochanteric osteotomy is universally used to overcome deformity in ankylosed cases.

Knee Joint Disease.—Perhaps the dictum of Sorrel can be taken in reference to the knee joint: in children, immobilize; in adults, resect; in the aged, amputate. Of course not every adult case should be resected. Amputation in the aged only shows our inability to stay the disease in the feeble. Deformity can be prevented by suitable apparatus and if present in ankylosed cases can be overcome by osteotomy or resection in many cases.

Ankle and Foot.—In the young, immobilization is still important. Arthrodesis or removal of bone affected, rarely in children and often in adults and the aged, may hasten the process of arrest.

Upper Extremities.—Not being weight bearing joints, surgical procedures are more frequently advised. In children, corrective apparatus and appliances should be given full trial before surgical

intervention is advised even when the disease is isolated to one small bone or joint.

Time Element.—The process of healing in tuberculous disease, like the onset, is slow and insidious. It requires six to eight months for the smallest bone or joint, and four to five years in the large bones or joints, even when uncomplicated. The rule of wearing supporting apparatus from six months to a year after all signs and symptoms have disappeared, is necessary and essential to procure arrest.

The Complications.—Deformities of various joints should be corrected and the parts placed in position to give the best function. Pott's paraplegia demands absolute rest and fixation preferably upon the Bradford frame. Paraplegia in children is not unfavorable because the granuloma about the cord usually absorbs with almost universal recovery. Paraplegia in adults is much more serious because the spinal cord in adults is usually surrounded by an abscess with an infiltration of white cells into the cord, and white degeneration of the cord occurs with permanent destruction and consequent paraplegia. Laminectomy in my experience has failed to relieve paraplegia, and fortunately is rarely used. *Abscesses* are not to be tampered with unless they become large and when uncomfortable because of size. In large cold abscesses aspiration is the rule, always endeavoring to keep the abscess closed. If an abscess should become secondarily infected it should be drained as any acute abscess. Pastes and antiseptic solutions in our experience are not to be compared with heliotherapy by sun and quartz lamps. *Sinuses* should be kept clean and secondary infection avoided as long as possible. Heliotherapy is our most valued agent in treatment of sinuses. *Amyloid degeneration*, the result of long continued suppuration, is a dangerous condition, but not necessarily fatal especially if suppuration can be stopped. In Minnesota we have seen after a summer's treatment with heliotherapy sinuses close and amyloid conditions disappear. *Meningitis* is a calamity which may be associated with tuberculosis at any time.

Differential Diagnosis.—In the differential diagnosis, tuberculosis should be confused only with pathological conditions that are slow in onset and very gradual in progress: chronic bone and joint lesions non-suppurative of the rheumatic type, chronic hypertrophic and atrophic; lues of bone or

joint; new growths; Von Perthes-Legg disease of the hip joint; bone abscess; chronic sprains; typhoid joints; joint abscess. The diagnosis of a tuberculous bone or joint condition is essentially the diagnosis of a chronic condition. A careful history, with intelligent interpretation of a roentgen-ray plate is of the greatest value. Laboratory aids, while of great value in the differential diagnosis, fail to be as convincing to me as the gradual insidious onset and characteristic bone atrophy, deformity and calcareous change seen in the usual radiogram of a tuberculous bone or joint. The positive diagnoses made in the laboratory are with the microscopical section and guinea pig peritoneal tests.

Heliotherapy can be used with considerable success even in Minnesota. The sun's rays beginning with two minutes' exposure in April is increased until the entire nude body is exposed to at least one hour's noon sun in mid-summer and fall; the quartz lamp is used in winter and on cloudy days. Apparatus should be used so the affected joint as well as the rest of the body can be exposed, sinuses and abscesses to receive close direct rays of the quartz lamp beginning with one-half minute exposure and the time lengthened to fifteen or twenty minutes or until signs of irritation appear. Heliotherapy is a most valuable adjunct in the hygienic treatment of tuberculosis. Good hygiene is essential. Sanitarium treatment is far superior to results obtained at home. Tuberculin in bone and joint cases is rarely used.

The old idea that an arrested tuberculous joint is a firmly ankylosed one is being superseded by a new idea that a tuberculous joint may be arrested without the disability of ankylosis. I believe this idea is coincident only with the much earlier diagnosis, earlier mechanical treatment and better hygienic and therapeutic measures now in vogue.

In conclusion we should remember the principle of treatment: rest, protection and good hygiene; treatment in children and young adults; resection of bones and joints of upper extremities in adults where a time element must be considered; fixation operations upon the spine only as an aid to outside immobilization and then after the age of seven and as operation of election; ever remembering that a tuberculous disease is cured by arrest and that the strength of arrest is coincident with the amount of calcification, encapsulation or cicatrization.

TUBERCULOSIS OF THE GENITO-URINARY TRACT*

HERMAN C. BUMPUS, JR.

Section on Urology

Mayo Clinic, Rochester, Minnesota

If it is recalled that tuberculosis of the genito-urinary tract embraces pathologic changes in eight complicated structures, many of which are bilateral, it will be realized how brief must be the reference here to even the most important of these changes.

INCIDENCE

The disease is most common between the ages of twenty and forty, but in any large series of cases approximately one-fourth of the patients will be more than forty. The incidence is twice as great in males as in females.

Fig. 1 (Case A158792). Areas of tuberculous calcification in an early case of renal tuberculosis.

SYMPTOMS

The usual symptoms of cystitis, frequency, dysuria and hematuria should always arouse a suspicion of tuberculosis. If these symptoms occur in early adult life, and do not readily respond to systematic treatment, the probability of tuberculous origin is greater.

In all cases of chronic cystitis a thorough urologic examination should be made, including the

Fig. 2 (Case A422611). Areas of tuberculous calcification simulating renal calculi.

examination of the urinary sediment for the bacilli of tuberculosis. Why urinary sediments are not thus examined as frequently as sputum is hard to understand; the technic is similar, and the opportunity to make an early, exact diagnosis is equal. It is true that care must be taken not to confuse the smegma bacillus, which is also acid-fast, with the tuberculosis bacillus, but if care has been taken in obtaining the specimen of urine, such contamination will seldom occur.

Authorities now believe that genito-urinary tuberculosis is secondary to other foci. Therefore, if the bacilli are not found in the urine, evidence of tuberculosis in the skin, lungs, glands, or bone should be sought and, if found, considered as added evidence. If the result is negative, the genital tract should next be examined because it will be found involved in 70 per cent of patients with urinary tuberculosis. There is no uniformity of belief as to which of the genital organs is usually invaded first, but clinical findings indicate that the disease will be found in the majority of cases in all structures. Such general involvement results because the pathologic changes produce little or no pain, and an epididymis that has gradually become swollen and nodular does not often attract medical investigation until a discharging sinus has resulted. When the disease has reached this point, it is usual to find the prostate nodular, with multiple tubercles, and one or both seminal vesicles thickened and enlarged.

TREATMENT

There is considerable diversity of opinion as to the form of treatment which should be employed. Young and others advise removal of the entire seminal tract, including epididymis, vas, prostate and vesicles, basing this advice on the fact that in approximately 50 per cent of cases, the disease becomes bilateral if allowed to progress, and on the theory that it originates in the seminal vesicles and spreads to the prostate and epididymis. Others find that the removal of the epididymis will be followed by quiescence of the infection in the vesicles and prostate. This has been our experience at Rochester. If it does spread to the opposite epididymis, its later removal is not difficult, and in many cases will not be necessary. Care should be taken not to operate too soon after the onset of tuberculosis in the genital tract, for there is a greater chance that miliary or meningeal tuberculosis will result if operation is performed while the infection is sub-acute.

DIAGNOSIS AND SYMPTOMS

If a thickened epididymis, with or without a sinus, has been discovered in a patient with intractable cystitis, the diagnosis of urinary tuberculosis is highly probable. If the epididymes appear normal, a rectal examination may show an early stage of the disease in the shape of a nodular prostate or inflamed seminal vesicle. If the genital tract gives no clue, a careful roentgen-ray examina-

Fig. 3 (Case A312890). Area of tuberculous calcification in an advanced case of renal tuberculosis.

tion of the renal areas may be as instructive as that of the chest. Braasch and others have pointed out that, in 20 per cent of cases, the tuberculous areas in the kidneys early become the site of lime deposit, and multiple small shadows resembling those that would be cast by particles of sand give evidence of renal involvement. As the disease advances, the areas of calcification become larger, and may make the distinction between tuberculosis and stone formation difficult. However, the areas of calcification resulting from tuberculosis have a more irregular outline, and their density varies throughout, while that of a renal calculus is apt to be uniform. Still later in the disease, the greater portion of the kidney may become calcified, but at this stage the diagnosis is usually apparent.

In the female patient, a vaginal examination often yields as helpful corroborating data in a doubtful case as does rectal examination in the male, for during the course of the disease the ureter from a tuberculous kidney quickly becomes much thickened and tortuous, and can be readily palpated through the vagina. Such a finding not only helps to confirm the diagnosis of tuberculosis, but indicates on which side it exists.

Urinary tuberculosis probably always commences as a unilateral disease, and although the first symptoms arise from the bladder, the initial site is usually in the renal parenchyma, which is infected in the majority of cases through the blood stream. The areas of infection usually appear in the cortex, are at first few in number and possibly single. They occur most often at either pole of the kidney, are at first distinct, separated by healthy parenchyma, but as the disease progresses, coalesce. As the tubercle enlarges, more of the parenchyma becomes involved, and a considerable area of caseation results. When the process reaches the pelvis or calyx, it breaks through and destroys the normal contour of the walls, producing the characteristic irregular moth-eaten appearance in the pyelogram. So characteristic of tuberculosis is this deformity, that any pyelogram which shows either the upper or lower calices irregularly filled, with a tendency for the pyelographic medium to exude into the cortex, should at once call to mind the possibility of tuberculosis.

If, added to these findings, the ureter is much dilated and tortuous, the evidence is much stronger. If pyelonephritis can be excluded, the diagnosis is unusually certain. In pyelonephritis, the irregu-

larity of outline in the calices is not so sharp, and occurs throughout the pelvis and calices instead of being confined to a single area. Also, pyelonephritis is generally bilateral, while a tuberculous infection remains unilateral for a long period. However, it is seldom necessary to resort to pyelography to establish a diagnosis of tuberculosis, as other cystoscopic findings are so characteristic, chief among these being cystitis. This has an entirely different appearance at different stages of the disease, but at every stage it is usually quite characteristic. If the involvement of the bladder is of recent occurrence, the inflammation is usually localized on the same side as the involved kidney, its greatest severity being found in the proximity of the ureteral orifice. In such early cases multiple small tubercles, resembling small pearls, are scat-

tered over the inflamed area. They may appear singly or in groups, and immediately surrounding them, the mucosa has a redness of the greatest intensity. As the disease progresses, these tubercles break down and, by coalescing, form multiple shallow ulcers throughout the inflamed area, which are characterized by a small slough that usually floats freely from them, and by the intensity of the surrounding inflammation. The density of the color immediately surrounding the shallow ulcers is seldom seen in any other form of cystitis. On distention of the bladder, the affected areas bleed

easily, and the greatest pain is produced by even slight distention. Such an area of ulceration and injection may be localized to a single area, but it is usually not long until the entire viscus becomes

Fig. 5 (Case A303068). Cystogram of a tuberculous bladder showing reflux up the ureter.

involved. After long periods of such involvement the walls of the bladder become so cicatrized that they lose all power of contractility, and the bladder is converted into a tissue incapable of its normal contraction, and holding but a few ounces of urine. The cicatrization at times becomes so extensive as to involve the urethral sphincter and produce permanent incontinence; in the female this usually occurs late in the disease, while in the male the same process develops multiple soft strictures, which are encountered when an attempt is made to pass a sound or a cystoscope.

In a goodly number of cases, however, the ulcerations in the ureter, early in the disease, result in stricture that occludes the lumen entirely. This produces what has become known as auto-nephrectomy and probably includes the only cases of renal tuberculosis in which the patients recover, except by surgical treatment. If this occlusion of the ureter occurs early in the disease, a history is often elicited of more or less severe cystitis at some time in the past, from which the patient has recovered. In such cases cystoscopic findings will reveal a stricture of one ureter, which at first gives the impression of being due to a calculus, but since a

shadow cannot be detected in the roentgen ray, the axiom is remembered that "a stricture of the ureter that should be due to stone, but is not, should be due to tuberculosis." In such a case the opposite kidney will be found to hyperfunctionate, the spurts of urine appearing very frequently, and if a test of renal function is made by means of phenolsulphonephthalein, 20 or 25 per cent may be recovered in fifteen minutes instead of the usual 15 per cent.

The removal of tuberculous kidneys, when encysted, might not be indicated, were one certain that they would remain encysted, but the danger of an extension of the disease through the capsule to form a perinephritic abscess, and the possibility of its acting as a focus from which the remaining kidney may become involved, demands its removal except in patients well past middle life.

Once a diagnosis of renal tuberculosis is made and the adequacy of the opposite kidney established, nephrectomy is indicated, for unless this is performed, the disease in time will become bilateral. It is imperative that nephrectomy be performed early, in order to give the bladder an opportunity to heal before too extensive ulceration develops. Before surgery is undertaken, however, it is wise to warn the patient that the removal of

Fig. 6 (Case A192791). Typical areas of tuberculous calcification in a fairly advanced case of renal tuberculosis.

the diseased kidney will not at once remove the symptoms from which he sought relief; that the cystitis will be slow in healing, and that the max-

imal improvement cannot be expected in less than two years. If improvement is not deemed sufficiently rapid, good results are often obtained by

ing kidney, which it was impossible to detect at the time of operation. Braasch, in a previous review, found the mortality for the first five years to be 20

Fig. 7 (Case A419323). Kidneys from a patient with bilateral renal tuberculosis. Note compensatory hypertrophy of the less involved kidney and characteristic cortical destruction of the other.

the lavage of the bladder with increasing strengths of phenol solution up to 6 per cent.

The risk of surgical treatment is not greater than that of general surgery. Sixteen deaths resulted from 678 nephrectomies for tuberculosis performed at the Mayo Clinic between 1894 and 1923, inclusive, a mortality of 2.3 per cent. Braasch and Scholl, in a recent investigation of the late mortality in cases of nephrectomy, found that more than half the deaths (13 per cent) occur during the first year, probably owing to disease in the remain-

per cent. The prognosis for recovery would, therefore, be 80 per cent, surely a gratifying result in so serious a disease.

GASTRO-INTESTINAL MANIFESTATIONS OF TUBERCULOSIS*

WALTER J. MARCLEY, M.D.
Minneapolis

In our conception of tuberculosis we keep in mind the fact that any manifestation of this disease in any tissue of the body other than the lung is, in the vast majority of cases in adults, coexistent with demonstrable pulmonary involvement or secondary to it. However, we may properly discuss gastro-intestinal manifestations in a symposium on non-pulmonary disease because:

1. In a certain percentage of these cases, either the pulmonary lesion is negligible as being inactive or is not clinically demonstrable.

2. Recent developments in diagnostic methods and in treatment have focussed attention upon these complications.

In the inception of tuberculous disease, when the bacilli and their products are beginning the contest with the natural resistant forces of the body, these forces are of the protective type and are reinforced more by the weapons of medicine than of surgery; but later on, as the natural defences fail, surgical intervention may come in and by physical and mechanical means remove those tissues that have been beaten in the contest and whose existence may be a menace to other vital parts. Thus has surgery for many years been winning the battle, especially in the chronic hyperplastic types of tuberculous enterocolitis.

During the past ten or twelve years, however, because of the development of roentgen examination and an improved treatment, there has been dawning a new era in our conception of the seriousness of tuberculosis of the gastro-intestinal tract. We now contemplate these conditions in a much more hopeful and courageous frame of mind than formerly obtained.

Incidence.—Some observers have found intestinal tuberculosis to be primary in from 3 to 5 per cent of all cases in adults; while in children it is primary in from 30 to 50 per cent and in the latter group the infection is usually of bovine origin. Lemon,⁷ in a recent presentation of fifty cases of tuberculous enterocolitis, finds in 14 per cent no primary focus in the lungs. He suggests that this

high percentage of primary intestinal disease in adults may be due to the fact that these patients come from a country where examination of animals for tuberculosis is a practice of recent development. It is generally considered, however, that even when the intestinal manifestation is the dominating feature, it is secondary to a tuberculous lesion elsewhere, in lung or gland tissues.

Tuberculous lesions of the mouth, pharynx and esophagus are very rare and seldom if ever primary. Actual tuberculous lesions of the stomach are also extremely rare, ulceration, the most common form, occurring but twice in 2,000 autopsies reported by Fenwick. The gastric lesions are found as miliary nodules or as single or multiple ulcers.

Tuberculous ulceration of the intestines has been found by ordinary methods of diagnosis to be exceedingly rare in early pulmonary disease. Schwatt and Steinbach¹¹ found, in 2,000 early pulmonary cases, a diagnosis of tuberculous enterocolitis was made clinically in only sixteen cases, or .8 per cent. In 135 advanced cases the diagnosis was made in thirteen cases, or almost 10 per cent. In 117 cases coming to autopsy they found forty cases, or 30 per cent. Other observers find 60 to 90 per cent of all pulmonary cases coming to autopsy showing intestinal lesions. Brown and Sampson,³ by roentgenological examination of the intestinal tract in pulmonary tuberculosis, give a much higher percentage of intestinal involvement than is diagnosed by ordinary clinical means.

Location of Lesions.—The lower portion of the ileum, the cecum and the appendix are most frequently involved, disease occurring here in about 85 per cent of all cases of intestinal tuberculosis (Conrath). However, tuberculous appendicitis exists as a disease peculiar and distinctive in itself in a small percentage of cases. It has been estimated that from 1 to 2 per cent of all appendices at operation are tuberculous. Margaret Warwick¹⁴ found at the University of Minnesota in post-operative examination of 210 appendices, approximately 1 per cent tuberculous. She emphasizes the wisdom of sectioning and examining carefully all appendices on removal, as demonstration of the tuberculous nature of the disease in the removed tissue may point the way to an early diagnosis of tuberculosis elsewhere in the body, with consequent early treatment.

Classification.—Tuberculosis of the intestines is conveniently classified in four groups:

*Presented in symposium before the annual meeting of the Minnesota State Medical Association, St. Paul, October 10, 1923.

1. Chronic hyperplastic tuberculosis which constitutes about 85 per cent of all intestinal tuberculosis in adults. It may be found in the terminal ileum, the flexures of the colon and in the rectum, but most commonly occurs in the cecum.

2. The ulcerative type, the common tuberculous enteritis occurring in children and as a secondary lesion in adults with advanced pulmonary disease.

3. The stenotic or cicatricial type which occurs usually in the small intestine.

4. The entero-peritoneal type which favors the ileo-cecal region, involving adjacent lymph nodes and peritoneum. In this form there is ulceration as well as hyperplasia of the bowel wall.

Symptoms and Diagnosis.—Disturbance of the gastro-intestinal function is very common in pulmonary tuberculosis. The question of diagnosis of intestinal involvement must be decided upon a general survey of the whole history and symptoms, more than upon one particular feature. Failing appetite, constipation, flatulence, feeling of discomfort in the stomach after eating are commonly present in patients who are developing intestinal disease. The leading symptom suggesting intestinal involvement is pain felt in the mid or lower abdomen, intermittent in character, suggesting gas pains, aggravated by food, relieved by fasting and persisting from day to day. Diarrhea may be persistent or may alternate with constipation. Pottinger⁹ mentions, as a suspicious symptom, the occurrence of stools only at night, due to changes in motility. The presence of diarrhea may be misleading, due to errors in diet causing intestinal catarrh. The finding of bacilli in the stools is of no diagnostic value, except in the absence of open pulmonary lesions. Whether a study of the symptomatology will determine what part of the bowel is affected and to what extent, there is some doubt.

In his series of 50 cases Lemon did not find that the symptoms indicated the location or extent of the lesions. Archibald,¹ by combining symptoms with findings by palpation, was able to formulate the following scheme of diagnosis:

"1. When the small bowel alone is involved, there is present constipation, often quite marked, and there is no thickening or mass, and in particular no tenderness to palpation localized in the cecal region.

"2. When the cecum, with or without the ascending colon, is involved, and the small bowel is free, there is present diarrhea or alternating constipa-

tion and diarrhea, and there is always to be felt a fairly defined thickening, sometimes even a mass, and there is a tenderness to palpation in the cecal region.

"3. When both small bowel and cecum are involved there is a mixture of the above signs and symptoms.

"4. When the transverse and descending colons are diseased in addition there are very rarely any signs that point to it; these are comparatively silent regions.

"5. When the appendix alone is tuberculous, it is not possible before operation to exclude the possibility of disease of the cecum. Between simple appendicitis and tuberculous disease it is often difficult to make a diagnosis; but it may be said that, where definite thickening of the tissues in the appendix region is felt, without there being an acute inflammatory reaction, and with a history of chronic slight pain and of occasional subacute attacks with persisting soreness, then the condition is much more suspicious of tuberculosis of the appendix, and possibly also of the cecum, than of simple appendicitis."

The roentgen diagnosis of ileo-cecal tuberculosis was first brought to notice by Stierlin¹³ in 1911. He stated that "the early as well as the later stages of the so-called cecal tuberculosis, can be diagnosed by this means, even in cases undiagnosable by the ordinary clinical methods." Other observers, notably Case,⁶ Pirie,⁸ Brown and Sampson,³ and Carman,⁵ verify this statement and present statistical evidence to show the inestimable value of a roentgen examination of the intestinal tract in all cases of pulmonary tuberculosis. Brown, Sampson and Hayes⁴ in 1922 report the results of their study based on 1,036 cases. "Hypermotility, localized or general, and filling defects were not the most significant findings," and they conclude that these data "indicate only ulceration of the colon which, when it occurs in a patient with pulmonary tuberculosis, is practically always tuberculous in nature. Persistent and recurring segmentation and dilation of certain loops of the small bowel are very suggestive of a similar lesion in this location."

With the aid of these roentgenological studies in diagnosis, treatment of these complications with or without surgical intervention, may be employed much earlier in the disease and with consequent happier results than formerly were obtained.

Treatment.—Tuberculous ulceration of the intes-

tine in the early stage is generally considered to be the problem of the physician. Healing may occur under the ordinary hygienic dietetic treatment in the sanatorium. While the chronic hyperplastic type offers greatest relief by surgical means, in the ulcerative variety, when it has failed to improve after a reasonable length of time under proper care and medication, and the pulmonary process is not so active as to contraindicate surgical procedure, great relief of symptoms may follow operation and permanent results are obtained in an encouraging number. Surgery is emphatically indicated when there are palpable masses in the ileocecal region associated with signs of chronic intestinal obstruction or when ulceration has gone on to cicatrization with stenosis of the intestinal lumen.

Surgeons report varying results depending obviously upon the extent and activity of the pulmonary disease and the location and extent of the intestinal complication. In Archibald's series of thirty-four cases of all types, the great relief from distressing symptoms in patients who would otherwise continue to suffer and the percentage of permanent results would encourage us to look upon this procedure with favor.

Ringer and Minor¹⁰ report thirty cases of intestinal tuberculosis treated by intravenous injections of calcium chloride with marked relief of symptoms in some cases. The authors believe this treatment prolongs life in some individuals and even may possibly cure the intestinal disease if diagnosis is made early. Other observers have noted similar results. Heliotherapy is of undoubted value in the treatment of intestinal tuberculosis. Dr. Bendes, of wide experience in the employment of this method of treatment, will discuss this therapy. However, at the risk of repetition I wish to emphasize the efficacy of artificial sunlight (the quartz lamp) in the treatment of these cases. In 1921 Blanchet² of Saranac reported twenty-five cases in which intestinal disease was diagnosed clinically and intestinal irritability demonstrated by the roentgen ray. Of these twenty-five cases, 40 per cent lost all symptoms and showed negative pictures with the roentgen ray after treatment. Stewart¹² reports seventy-seven cases treated by the quartz lamp, with improvement in 66 per cent. The experience of other clinicians is varied. The writer has used the ultra-violet ray in a considerable number of cases with encouraging results.

Although we cannot frequently check up our diagnoses by post-mortem examination—which fact is perhaps the best evidence of the efficacy of the treatment—the present-day clinical and roentgenological methods of diagnosis are sufficiently accurate upon which to base the claim of beneficial results obtained by this therapy.

CONCLUSION

1. Intestinal tuberculosis may occur in the absence of a demonstrable pulmonary lesion, but is usually a complication of disease in the lung.

2. Healing may take place under medical treatment.

3. Roentgenological examination of the gastro-intestinal tract should be made in all cases of pulmonary tuberculosis.

4. Surgical intervention greatly relieves distressing symptoms and may produce permanent results.

5. A careful examination of all appendices removed by operation would reveal tuberculosis in at least one per cent of all cases. Any means of diagnosing this disease should not be overlooked.

6. Improved diagnostic methods and favorable results from treatment by natural sunlight and quartz lamp therapy greatly augment our hope and courage in the treatment of this serious condition.

HELIO THERAPY IN THE TREATMENT OF TUBERCULOSIS*

J. HARRY BENDES, M.D.

Assistant in Medicine, University of Minnesota
Assistant Medical Director, Glen Lake Sanatorium
Oak Terrace, Minn.

Heliotherapy is that branch of medical science which treats of the application of the sun as a remedy in the treatment of disease. Locally its application is characterized at first by a feeling of warmth, then a slight erythema, followed by a chronic congestion and finally a pigmentation.

The idea of modern heliotherapy was conceived by Rollier. In 1903, he opened a clinic in Switzerland and formulated a technique, which has stood the test for twenty years. There have been as many deviations and improvements in his technique as there are heliotherapy workers in Europe and America. Every man who starts a clinic for heliotherapy thinks he should improve on Rollier's technique and have a little private one of his own. Rollier's technique has been used for twenty years and after following it almost ten years, I, personally, cannot see why one should deviate from it. In fact, it should be adhered to more closely. Heliotherapy does not mean turning a patient out into the sun indiscriminately; it means giving carefully supervised sun baths.

The great obstacle in treating extra or non-pulmonary tuberculosis is that this type of tuberculosis is looked upon as a local disease, and is referred to the surgeon or orthopedist, and the fact that it is a general constitutional disease with local manifestations is entirely ignored.

The technique of heliotherapy is as follows:

Rollier started out by zoning the body, as feet, legs, thighs, abdomen and chest, giving each zone its therapeutic dose of sun.

On the first day, insolate (expose to the sun) the front of the feet as far as the ankles for five minutes; at the end of five minutes, roll over and expose the back part of the feet the same way for five minutes. Then cover up and rest one hour. At the end of one hour, repeat the insolation and at the end of this second exposure, the sun bath is finished for the morning of the first day. That afternoon, repeat the insolation the same way as in the morning.

On the second day, expose the anterior part of the feet as far as the ankles for five minutes. At the end of five minutes, carry the exposure up on the legs as far as the knees for another five minutes. At the end of ten minutes, roll over and insolate the back part of the feet and legs in the like manner. Two exposures in the morning and two exposures in the afternoon at one hour intervals.

On the third day, insolate the anterior part of the feet for five minutes. At the end of five minutes, carry the insolation up on the legs as far as the knees for another five minutes and at the end of ten minutes carry the insolation up on the thighs for five minutes. At the end of fifteen minutes, roll over and insolate the back part of the body in a like manner. Give two insulations in the morning and two insulations in the afternoon at one hour intervals.

On the fourth day, insolate the anterior part of the feet for five minutes; at the end of five minutes, carry the insolation up on the legs for five minutes. At the end of ten minutes, carry the insolation up on the thighs for five minutes; at the end of fifteen minutes, carry the insolation up on the abdomen. At the end of twenty minutes, roll over and insolate the back part of the body in a like manner. Do this insolation twice, once in the morning and repeat the insolation in the afternoon.

On the fifth day, insolate the anterior part of the feet for five minutes; at the end of five minutes, carry the insolation up on the legs for five minutes; at the end of ten minutes, carry the insolation up on the thighs for five minutes; at the end of fifteen minutes, carry the insolation up on the abdomen for five minutes; at the end of twenty minutes, carry the insolation up on the chest for five minutes; at the end of twenty-five minutes, roll over and expose the back part of the body in a like manner. This insolation is carried out once in the morning and once in the afternoon.

On the sixth day, repeat all the insulations as on the previous days, but increase the chest insolation to ten minutes both front and back.

On the seventh day, do all the previous insulations, but give the chest fifteen minutes both front and back.

Each day, increase the insolation by successive five minute steps until the fourteenth day.

On the fourteenth day expose the whole body for fifty minutes; on the fifteenth day for fifty-five minutes; on the sixteenth day for sixty minutes;

*Presented in symposium at the annual meeting of the Minnesota State Medical Association, St. Paul, October, 1923.

on the seventeenth day for sixty-five minutes; on the eighteenth day for seventy minutes; on the nineteenth day for seventy-five minutes; on the twentieth day for eighty minutes; on the twenty-first day for eighty-five minutes; on the twenty-second day for ninety minutes.

Now, though we find that by this graduation we are able to give three hours of sun at one time, and in some cases even four and five hours, still we do not advocate giving that in all cases, but only in cases where the tolerance is found to be great enough. After a pigmentation has taken place, large doses of sun can be given without deleterious effects.

The usual treatment is three hours of sun at one and one-half hour periods, especially, in high typed blonds, red-haired persons, the emaciated, the children and the aged.

On the fourteenth day, total exposure. The treatment is divided into two periods of ninety minutes each, forty-five minutes on the back and forty-five minutes on the anterior part of the body. Two such treatments are carried out daily, one treatment in the morning and one treatment in the afternoon. When the patient is able to withstand this amount of sun without any unpleasant effects and when his general condition starts to improve, more sun can be given up to four and five hours.

Some patients react more favorably to frequent short exposures instead of too long exposures, especially those who are inclined to burn. In the latter cases, the pigmentation will take place more rapidly, if four one-hour exposures are indulged in instead of two two-hour exposures.

An ice cap to the nape of the neck and a cold compress over the heart alleviates symptoms in cases who become fatigued easily and who suffer from exhaustion and palpation.

The technique used at Glen Lake Sanatorium is the same as the one followed by Rollier, with this exception: Dr. Rollier allows his patients to rest for a period of from fifteen to twenty minutes between exposures, but we have found that in most cases this is too short a time. If the patients have not had sufficient rest they become exhausted. Twenty minutes of rest between exposures should be the minimum time. A longer period is much better. When a patient starts routine sun cure we have him rest for an hour between exposures. He should not be tired after a treatment, but should feel invigorated. If patients are tired after a sun

bath, they have been exposed too long a period or they are not reacting favorably to the treatment.

Some of the accidents of faulty technique are: headache, nausea, vomiting and fatigue. Here I might mention that the sun rays will cause fatigue just as voluntary exercise does, if indulged in indiscriminately. The safest method is graduating the patients as we do.

Different individuals react differently to the sun. All patients cannot abide strictly by the routine treatment as it is prescribed by the physician. The susceptibility of the individual must be taken into

consideration. Some patients can stand a faster graduation than the one prescribed, but there are others who cannot tolerate it, especially the blonds, the red haired, the emaciated and the febrile cases of pulmonary tuberculosis. In these cases, the progress is even slower. We generally start them on periods of exposure of two minutes on each zone, but we have had cases where even two minutes of exposure has proven too much.

The exceptional cases, as mentioned before, should be watched constantly so that they do not

burn. At the first sign of redness the patient should be covered and taken out of the sun. In case a burn follows, it is accompanied by a sense of burning, itching and smarting, and in some cases the patient will run a high temperature and pulse. Generally this condition lasts for about three or four days and then disappears. The patient is then kept out of the sun until all signs of a burn have disappeared and his temperature and pulse have returned to what it was before the accident occurred. A temperature resulting from a burn is contra-indicated for sun cure. When the patient is again started on his treatments, he should be started a few steps back from the time when sun baths were discontinued. As I said before, these cases should be watched constantly so that they will not burn, because if they do, the progress of the treatment is interrupted and much valuable time is lost.

When Rollier instituted heliotherapy it was for the purpose of curing surgical tuberculosis. Since then it has been used and advocated as an adjunct in the treatment of metabolic disease and some individuals even go so far as to prescribe heliotherapy when they have exhausted all other ethical, medical and surgical skill at their command.

After cases of surgical tuberculosis have passed through the operative and plaster paris stage and find their way into the Sanatorium, they usually have a pulmonary lesion complicating the surgical one and also in many cases there are abscess formations and draining sinuses due to secondary infection.

It is because of these cases of surgical tuberculosis complicated by pulmonary tuberculosis in all stages of the disease including some with cavity formation that we are varying just this much from Rollier's technique.

We take temperature and pulse because those two factors are the "stop, look and listen" sign post of activity and also of excessive sun. This is done as follows:

Temperature and pulse are taken immediately after the sun baths and again one-half hour after the sun bath, while the patient is resting. If there is one degree elevation in temperature or a marked increase in pulse rate after the half hour rest, it means that the patient is getting too much sun and the treatment is dropped back a step or two to the point where the patient reacted favorably. The procedure is carried out as long as a patient is on

sun. We know that this is important and the observation should begin as soon as the patient starts sun cure.

If a patient gets a headache, becomes dizzy or becomes nauseated while taking sun, the sun bath should be discontinued immediately and the patient kept in his room or in the shade until he has been relieved. If he remains in the sun in spite of these symptoms, there will be a gastro-intestinal disturbance lasting from a few days to even possibly a week.

The initial sun bath is not taken until the patient has become acclimatized. Generally this takes about two weeks. During this time the patient is studied, the range of temperature and pulse is watched, the heart and lung condition is studied, blood and urine conditions noted. Wassermann and other tests are made. During this time, the patient becomes accustomed to the light and air, and has also learned through observations and instructions some idea of how the treatment is carried out and what is expected of him.

Before a patient starts his daily treatment he takes his temperature and pulse. Immediately after the sun bath he again takes his temperature and pulse, and then again, one-half hour later. So if an acute condition occurs we can tell just which sun exposure was the cause.

One of the principal factors to be taken into consideration in giving heliotherapy is the source of the sun. Early morning sun is desirable and it is best to avoid the hottest time of the day and the direct rays of the sun. White linen should be used as a covering on the bed because it intensifies the sun's rays.

Certain precautions should be taken while the patient is taking the sun bath. The head, especially the nape of the neck, should be protected from the sun's rays. This can be done by means of an awning, a wide-brimmed hat, or a sunbonnet. These precautions should be carried out except in special cases when the patient is instructed to expose his face to the sun. Even then, when exposing posteriorly, he should cover the nape of his neck. We have made several attempts to dispense with the ice cap or wet cloth at the nape of the neck and over the heart. This can be done in the majority of cases but there are some cases where it is still absolutely necessary.

The patients should always wear dark glasses, black being the best. If they do not they may con-

tract conjunctivitis. They should also be protected from the wind at all times.

When starting the sun baths it is necessary to go slowly. The time is gradually increased until a pigmentation has been obtained resulting in a mahogany brown. Then the exposures can proceed more rapidly and longer periods to the sun can be given, even as much as four or five hours at a time.

The reason for this method is described by Rollier as "By this means we are able to get a general idea of the tolerance of the patient to sunlight before the more vulnerable parts of the body are exposed; any accidents which result are therefore of a slight nature, and as they only affect outlying regions of the body, their general effects are likely to be minimal. The thoracic and abdominal viscera are not subjected to any congestion but rather to a decongestive action, as insolation of the extremities causes the blood to flow to these regions and therefore away from the viscera."

In the various locations of the disease, orthopedic position is maintained by means of pillows, boards and extension apparatus. No casts are used.

During the course of pigmentation various things happen. All patients do not respond in the same manner. The sequences of occurrences that take place are numerous.

I will endeavor to explain to you just what takes place when a patient is first exposed to the sun. I will begin with the action of the sun upon the skin, and then follow with the action of the sun upon the individual.

The action of the sunlight upon the skin is in proportion to the length of time and the intensity of the light. At first, there is a dilatation of the superficial capillaries in the skin. This produces an erythema which gradually shades into a bronze hue, then turns to a copper color and finally turns into a chocolate brown.

During the first five or seven days of treatment the first noticeable perception is a branny desquamation of the skin, which brushes off like dandruff. This desquamation is nothing more than dead skin. After that the various steps in the pigmentation follow.

During this erythematous stage there may be an itching of the skin, which varies from a very slight itch to a painful affair coming on in from six to thirty-six hours. This itching usually clears up by another exposure to the sun. Aside from being an

unpleasant symptom, there is no danger associated with it. If a temperature and fast pulse occur along with the itch, you can be sure the patient has been burnt and the burn will manifest itself on the second day with exfoliation of the skin.

The rôle of pigmentation is protective. It is a protection against burns and infection and against the irritating ultra-violet rays and it enables the body to withstand large doses of sun without any bad effects to the patient.

At first the skin is very white, and sickly looking. It is cold and clammy to the touch and resembles putty. When the pathologist attempts to obtain a drop of blood for a blood count he does so with difficulty. He must make a deep puncture in order to obtain sufficient blood for an analysis. After a few treatments the skin becomes warm and glossy, and finally becomes soft and velvety, bleeds easily and heals very rapidly. Infection and bed sores are unknown to sun patients. In some cases, edema of the part will occur. In others, there will be the formation of minute vesicles filled with a clear fluid, especially on bright days when a hot wind is blowing. These are just a few of the things that occur during the course of the tanning. In some cases, they do not call for special treatment; in others they do.

According to Kisch, after pigmentation takes place, there is seven times more blood in the skin than there was before starting sun treatments.

Under the influence of the sun, hemoglobin is increased, the sweat glands are stimulated and the organs of internal secretion are accentuated.

As for burns, I have taken the Thézac Porsmeur lens and focused it upon pigmented skin. After fifteen minutes, there was an erythema on the pigmented skin which disappeared in about one hour, while upon unpigmented skin a burn took place with blistering which lasted for several days.

When a patient first starts sun cure there is generally a loss of weight. This is due to poor appetite, a loss of water from the stimulated sweat glands and kidneys, and the general cachectic state. After the tenth day, the body becomes accustomed to the action of the light and air. The patient's appetite returns, and the weight that was lost in the first ten days is rapidly regained, usually in the same length of time in which it was lost.

In giving heliotherapy to surgical cases, we do not use casts or splints, but immobilization is obtained by means of traction and extensions. If

casts and splints were used the part of the body affected would be covered and no benefit would be derived from the sun, light and air. It is necessary that every part of the body be exposed to the sun if the patient is to receive any benefit. When a surgical case who is in traction is put out on the porch for sun, all apparatuses are removed, so that every part of his body will be exposed. When casts or splints are used, the muscles and tissue of the part encased in a cast will atrophy; on the other hand, when a patient is put in traction, the traction is removed once a day, and the patient's limbs or whatever part of the body is in traction, is massaged, so the muscles will not atrophy. In cast or splint cases an ankylosis generally takes place. In heliotherapy, we strive to obtain a cure with restoration of function.

Patients are allowed to drink all the water they care to while taking the sun bath. As yet, no harmful results have been noticed. As for food, we give our patients their breakfast while they are taking their sun baths. Last summer we tried giving them their dinners while in the sun and we did not have one gastric upset. So far, this year none of the children or women have experienced any intestinal disturbances. They have all had four hours or more of sun daily and have had both their breakfasts and dinners while taking the sun bath. Among the men, we have had a couple of complaints of nausea, I believe, due to eating while in the sun. These patients lay the disturbance to some other cause than the sun, but personally I believe the sun was the causative agent.

Recently my attention was called to the danger of sterility in those patients taking heliotherapy, especially in case of genito-urinary tuberculosis. This idea is erroneous. A loin cloth (not a bathing suit) is worn only as a matter of decency and not to prevent sterility. If sterility occurs it is due to some underlying pathological condition and not to the sun's rays. What better evidence have we than the Indian? One of the differences between a white man and an Indian is that the white man is face from his neck up while an Indian is all face.

Air and altitude do not play an important rôle in heliotherapy. The main principle in the treatment is simply to use the sun whenever it shines. A great many false impressions are formed by casual observers when they learn that children take heliotherapy during the winter. There is

nothing remarkable about this and false impressions should not be formed. In the first place, all the children during the winter have heavy overcoats of tan. They have lived in the open, their skin has been accustomed to the light and the air and when the thermometer drops to around freezing, those children who have had heliotherapy do not mind it. Secondly, the patients are not exposed in the winter unless the sun is shining, the day is not too cold, and there is no wind blowing. If a patient complains of being cold, he is immediately covered up.

A few facts to remember are:

1. Sunshine without rest is worthless.
2. Sun cannot be taken through glass or screen.
3. Patients cannot come to your office for artificial sunshine and expect to get well.
4. The mother, aunt, or sister cannot supervise the taking of sun any more than they can supervise the routine sanatorium care for pulmonary tuberculosis.
5. It takes trained workers to supervise heliotherapy.
6. In cases of bones and joints it does not mean operation, but it means applying orthopedic and surgical sense to heliotherapy.
7. Cancer and syphilis will not get well with sun treatment.
8. Remember that rest is just as important as sun.
9. The time of day, the season of the year, the character of the patient, and the amount of pulmonary tuberculosis must be taken into consideration.
10. No tan, no cure. The greater the tan the sooner and better the cure.
11. Sun cure does not cure all cases of surgical tuberculosis and a certain percentage fall by the wayside.
12. Hemorrhagic cases must be watched carefully and the time periods are cut to two-minute exposures instead of five-minute.
13. Genito-urinary tuberculosis cases are given tuberculin along with sun. We use Koch's O. T. and give it according to Pope's logarithmical scales.

In all cases of extra- or non-pulmonary tuberculosis, remember the following: If you are loath to dispense with casts, bivalve and remove

them during sun cure. Do not cover a hip with a cast and expect to give sun cure through it.

If you think you must operate, hesitate, give heliotherapy its opportunity first. Then you will operate only in very exceptional cases.

DISCUSSION ON THE FIVE PRECEDING PAPERS

DR. W. S. LEMON, Rochester: A symposium of this character cannot fail to impress one with the far flung attack of the bacillus of tuberculosis. It is true that the organism affects certain tissues more frequently than others, as evidenced by the preponderating incidence in the lungs, yet few tissues are exempt. The symptoms are the expression of a reaction of the tissue involved and represent the physiologic possibilities of that structure. It is not strange, therefore, that the evidences of activity vary and indeed are as different as are the reaction possibilities in the skin from those in the bowel, or those of the genito-urinary apparatus from those of bone.

It must be granted, of course, that the diagnosis has been proved by physical and laboratory examination, or by the use of tuberculin, or by histologic investigation of infected tissue. The first method is best designed to determine whether or not activity is present, because symptoms resulting from activity are a better guide to the diagnosis of an active lesion than are the physical signs or often the laboratory tests. In fact, constitutional symptoms may appear days or weeks even before recognizable anatomic changes have taken place.

The fundamental functions of the body are affected in much the same way regardless of the location of the lesion. Thus in a study of tuberculous enterocolitis, I found that the pulse rate, blood pressure and weight of patients were about equally affected, regardless of the location of the lesion in the bowel, or whether the lungs or other organs were likewise invaded by the bacillus of tuberculosis.

Tuberculosis is first of all a focal disease. The reaction to the bacillus produces an avascular cellular morbid structure lying within the tissue, and whether within lung, skin, kidney, bone or bowel, separated from it by a protecting layer of greater or less permeability, depending upon the degree of success of the protective mechanism of the particular individual infected.

One other factor of importance is connected with the possibilities of constitutional symptoms, namely, the activity of the enveloping structures. In this regard, Krause says: "It would seem that the intoxication of tuberculosis, in the natural evolution of the infection, is in large measure a nonspecific process brought about by the absorption of material from foci in amounts large enough to produce symptoms."

It is possible that the bacteria themselves or their degraded forms, or the products of the cellular material forming a focus, may produce intoxication and constitutional symptoms if the surrounding structures are in a physiologic state to favor absorption through vessel or lymph channel. Given an open vessel, a lymph channel or other channel of communication and bacilli may spread from a primary focus to other organs of the body. Im-

mediately, the tissues being hypersensitive, there is an outpouring of inflammatory elements, and acute reinfection is clinically diagnosed from the constitutional symptoms due to their absorption.

Thus the patient with pulmonary disease progresses badly in spite of good treatment when the kidney becomes involved from hematogenous infection, or equally badly when the bowel is involved, probably from the ingestion of germ bearing sputum. The later symptoms expressing the location of this process depend upon the interference with the physiological activities of the area damaged. In the skin these are expressed often as signs rather than symptoms and may be evidence of true histologic tuberculosis as in lupus vulgaris or as a localized nonspecific inflammatory reaction, as in the tuberculids. These latter may be compared to a tuberculin reaction, which is primarily an immune reaction associated with an acute focal inflammation. Stokes says: "They are cutaneous reactions to hematogenously distributed tubercle bacilli deposited in a hypersensitive skin and originating in a tuberculous lesion sometimes unrecognized."

I am confining my remarks entirely to a general consideration of tuberculosis rather than to its attack upon the various organs. Underlying all is a fundamental fact that we are dealing with tuberculosis itself, that the symptoms described are but the reaction of the tissue attacked, and are as varied as are the physiological functions of the several organs.

Dr. Bendes was good enough to let me have his paper before coming to this meeting and I wish I could add anything to it. It seems to me that he has described in detail in such a thorough way that anything that I might say would be superfluous. Anyone who is acquainted with the Rollier type of management and with the character of the Rollier treatment must know that he put into our hands a very useful weapon in the control of tuberculosis.

I have attempted to open this discussion by the mere use of generalities which will cover the diverse forms presented in the papers of the symposium. I wish to leave to the members of this society the privilege and the right to discuss the particular form that claims their interest.

DR. M. GEORGE MILAN, Thief River Falls: I desire to make a few remarks on the subject of non-pulmonary tuberculosis, particularly with reference to the paper presented by Doctor Marcle on gastro-intestinal manifestations of the disease. I imagine that Doctor Marcle did not have time to include in his paper points relative to diet in the care and treatment of these manifestations. I, myself, have come to the conclusion after six or eight years' observation in sanatorium work of cases wherein a gastro-intestinal complication accompanies pulmonary tuberculosis that we can do as much with diet in many of these cases as we can accomplish with any other single method.

The procedure in treatment to be followed from the dietary standpoint depends mainly upon two factors: first, attempts must be made to lessen irritation in the intestinal tract; and, secondly, we must bring into play any method by which peristalsis can be decreased and maintained at a level coincident with a normal functioning of the intestinal tract itself. Success in the handling of this

second factor will be dependent to a great extent upon our efforts in lessening local irritation. I have found that many patients when given milk in excessive amounts will develop indigestible curds in the bowels which in turn set up irritation. Well done meats, as well as sauces and preserved fruits, will often produce intestinal irritation in a great many of these patients.

We must not confuse ordinary dyspepsia with tuberculous enteritis. In a great majority of the pulmonary tuberculous cases that are complicated with gastro-enteritic disturbances tubercles are found in the intestines. It does not necessarily follow, however, that because evidence of tuberculous infection is found in the intestinal tract the gastro-intestinal disturbance is necessarily a clinical tuberculous enteritis. There is little question that when the pathology of these tubercles shows a state of activity the enteritis is probably due to the tuberculous condition. However, in the mild cases the intestinal tubercle may be found and still, being of a healed type, may not be causing any disturbance even though gastro-intestinal manifestations are present in the patient. In other words, even in the intestinal tract we must differentiate in the presence of tuberculosis whether there is clinical tuberculous enteritis present or only intestinal tuberculous infection without any clinical manifestations. When the first signs of abdominal trouble appear we must endeavor by all our available resources to learn whether or not it is the tubercle that is at the base of the enteritic trouble, or some non-tuberculous condition complicating the pulmonary lesion.

DR. H. T. HELMHOLZ: I would like to say a word about the cutaneous tuberculin reaction. I think the pendulum has swung too far in the opposite direction, in that we rely very little on a positive or negative tuberculin reaction. I think that is true if we use it in the way that it is ordinarily used, merely one or possibly two tuberculin reactions, according to Pirquet. As you all know, a positive tuberculin reaction means merely that some time or other the individual has had an infection with the tubercle bacillus. On the other hand, a negative tuberculin reaction, I believe, is of definite value, providing it is properly done.

One, two or more Pirquet reactions mean nothing. A gradual increase in the dosage of an intracutaneous reaction that remains negative even when as much as one or two milligrams are given I feel sure is of very definite value in excluding tuberculosis. We all know that miliary tuberculosis does not give a positive Pirquet reaction, but, if the dosage is increased, as has been shown by Hamburger and Casparis, even in those cases one can obtain intracutaneous reactions. Just recently we had an

experience with a different type of case where the tuberculosis was so completely healed that there was no reaction. In this case of tuberculosis of the spine we increased our dosage because we thought we were unquestionably dealing with tuberculosis. With one milligram of tuberculin given intracutaneously we obtained positive tests. So I feel that a negative tuberculin test, if properly carried out, is of great help in excluding tuberculosis.

DR. J. A. MYERS, Minneapolis: No one who has observed Dr. Bendes' patients at the Glen Lake Sanatorium can question his splendid results. Although the changes which occur in the body of the tuberculous treated by heliotherapy are not as well understood as in rachitic cases so treated sufficient data have accrued on the subject to prove that it deserves a very definite place in tuberculosis therapy. In my opinion heliotherapy has four distinct effects upon patients: first, the chemical action of the rays; second, a period of almost absolute rest which many patients would not take otherwise; third, a daily air bath which is of unmistakable value in treating tuberculosis; and fourth, the psychic effect. The patients feel that something is being done for them and often will remain under treatment much longer and consequently develop more permanent healing than otherwise would be obtained.

Every practitioner of medicine who treats tuberculosis should become familiar with the technique and the indications of heliotherapy. Too often we think such special procedures are for institutions and have no place in private practice. This is far from true and in fact would be undesirable. When we consider the large number of tuberculous patients in this state and the small number of sanatorium beds, it is obvious that more tuberculous patients must be treated by private physicians than by sanatorium physicians. Often it is a long time after an application is filed until a patient can be admitted to a sanatorium. It is not right that during this waiting period patients should be deprived of such special therapy as heliotherapy if it is indicated. Again, very few patients are cured in a sanatorium, but most of them return to their homes for a long period of convalescence during which time they are under the care of their private physicians, where indicated heliotherapy should be continued in the home.

In Minnesota considerable natural sunlight is available during the spring, summer and autumn months. On cloudy days and during winter months artificial sun lamps may be used in the homes. In every case heliotherapy in the home must be under the most careful guidance of a physician who not only prescribes the dosage but also keeps the patient under very close supervision.

PROBLEMS ENCOUNTERED IN THE TREATMENT OF DISEASE OF THE BILIARY TRACT*

E. STARR JUDD, M.D.

Rochester, Minnesota

The results of operations performed for gallstones and inflammation of the biliary tract are, as a rule, satisfactory. Few fields of surgery offer as good results as does this one. There are certain problems which we are constantly encountering, and with which we are doubtless making some headway, but it is not always possible to secure the desired results. Our present ideas of the source of infection, and the manner in which it is distributed to the adjoining tissues are so different from our former conception that they may eventually help us to solve some of the problems. Inflammation of the liver, and probably also of the pancreas, in association with infection of the gallbladder, may account for the persistence of symptoms in some cases, or for their recurrence after the gallbladder has been removed. At present, it does not seem that this conception will change our plan of surgical treatment; however, it does suggest that the choice of procedure is the removal of the gallbladder.

Generally the clinical symptoms in cases of disease of the gallbladder are very definite and clear-cut, and a positive diagnosis can be made in most cases. Occasionally, however, the usual gallbladder syndrome is present, and yet at the time of operation it is impossible to find sufficient evidence of inflammation in the gallbladder or biliary tract to explain the symptoms adequately. In some cases, undoubtedly, the diagnosis has been incorrect and the symptoms were due to a lesion elsewhere; in others, I believe the trouble does exist in the biliary tract, but is not yet recognizable, as in early cases of primary hepatitis in which the gallbladder is only slightly involved; or in early cases of primary pancreatitis. Since we have been making careful observations on the condition of the liver and the pancreas when operating for gallbladder disease, we are recognizing changes that often exist in association with cholecystitis, which formerly were not interpreted.

SYNDROME OF CHOLECYSTITIS WITHOUT MUCH INFLAMMATION IN THE GALLBLADDER OR IMPROVEMENT AFTER CHOLECYSTECTOMY

The symptoms in the following case (Case 1) led to the belief that the patient was suffering from cholecystitis. In spite of the fact that the findings were not definite, it seemed best to remove the gallbladder, and this was done some months ago. The patient reports that her condition is not much improved. This does not necessarily mean that the operation was a failure, for if she was suffering from a chronic hepatitis or pancreatitis, it is still possible that she may obtain relief through the operation. However, it is also possible that our interpretation of the case was not entirely correct.

Case 1 (A428477). Mrs. E. M., aged forty-three years, had had marked gastric disturbance for twelve years, characterized by irregular attacks of colic and belching of gas. Five years before coming to the Clinic, she had had a severe epigastric colic, with pain referred to the right shoulder. Morphine was necessary to control the pain. Residual soreness in the gallbladder area and slight jaundice followed. She had had many minor attacks since that time. She was markedly constipated, and it was necessary to regulate her diet.

The findings at examination were essentially negative. At operation, July 13, 1923, the gallbladder was found buried in adhesions and involved in a moderate inflammatory process. There was moderate hepatitis. Cholecystectomy was performed. The patient's convalescence was uneventful.

CLINICAL SIGNS OF GALLBLADDER DISEASE WITHOUT MUCH EVIDENCE AT OPERATION OF DISEASE IN THE BILIARY TRACT

More than once, after a diagnosis of gallbladder disease had been made, I have had occasion at operation to refuse to do anything with the gallbladder because it appeared normal. However, some of these patients have returned in a comparatively short time because of the persistence of their trouble, and have been relieved by secondary removal of the gallbladder. Our experience suggests that inflammation may exist in the gallbladder or biliary tract with little if any gross evidence of it. In the future it may be possible to recognize the conditions which cannot be interpreted at the present time. In some cases in which gross evidence of trouble was not sufficient to warrant cholecystectomy, the gallbladder was opened and a specimen excised from the wall for microscopic examination. In an endeavor to reach a proper conclusion with regard to these cases, the ease with

*Read before the Minneapolis Surgical Society, January 10, 1924.

which the gallbladder may be compressed, the thickness of the wall, the character of the bile, and the amount of fat deposit in the wall as an indicator of a chronic inflammatory process, have been considered, but even these details do not seem to help materially. Case 2 illustrates the type in which there are clinical signs of disease in the gallbladder without much evidence of disease at operation:

Case 2 (A445832). Mrs. R., aged twenty-five years, had had attacks of epigastric pain, every four to six months for four years. They lasted about a day, were accompanied by severe vomiting, and were often followed by slight jaundice, lasting a week. The pain was not referred, but was so severe as to require hypodermics. Between attacks, the patient had considerable gaseous dyspepsia with intolerance for greasy foods. During the last two years the character of the distress had changed somewhat, localizing at times (about a week prior to the menstrual period) in the right lower quadrant.

At examination the urine and blood findings were normal. The x-ray of the stomach was negative. Gastric analysis revealed total acidity 40, and free hydrochloric acid 20. At operation, November 6, 1923, very slight cholecystitis was found; chronic catarrhal appendicitis was present. The gallbladder and appendix were removed. The convalescence was uneventful.

SUBACUTE CHOLECYSTITIS, RUPTURED GALLBLADDER, WITHOUT MARKED SYMPTOMS

Case 3 is in direct contrast to Case 2, and illustrates how extensive the infection in the biliary tract may be without producing severe symptoms. The patient had never had sufficient pain to disable her to any extent, and at the time she presented herself at the Clinic, her examination was essentially negative, although it seemed from the history that she might have a mild degree of cholecystitis. At operation a day or two later, a ruptured gallbladder was found, many stones were present, and the infection, although of low grade, had a tendency to spread and form abscesses, which shows that a patient who has cholecystitis should, under ordinary circumstances, be operated on.

Case 3 (A445069). Mrs. D., aged forty-three years, had had a drawing feeling in the epigastrium with loss of appetite and moderate dyspepsia for two years before coming to the Clinic. She had dieted. There had been a loss of 35 pounds in weight. One month before, she had had an attack of generalized abdominal pain lasting one-half hour, and relieved by hot applications. She had vomited once, but had never been so disabled that she was obliged to go to bed.

The findings at examination were essentially negative, except for tenderness at the umbilicus. There was no free acid in the stomach. The condition was diagnosed as a possible cholecystitis. At operation, October 25, 1923, an

empyematous gallbladder, which had ruptured into the liver, was found. There were many stones. The appendix was inflamed. Cholecystectomy and appendectomy were performed. Two Penrose drains were inserted.

The convalescence was uneventful.

ACUTE GANGRENOUS CHOLECYSTITIS

One of the problems of interest in connection with the study of these cases is the rapidity with which the gallbladder may become gangrenous. At the time of the operation, there is generally a little ascites, the gallbladder is usually practically free from adhesions, but tense and thick, and when removed, the mucous membrane is black and necrotic, apparently entirely devoid of circulation. It is possible that a stone (in cases of cholelithiasis), or an inflammatory process, may obstruct the neck of the gallbladder and interfere with the circulation, although when a stone blocks the cystic duct, a hydrops of the gallbladder usually results. It is more than likely that, in these acute gangrenous conditions, emboli form in the vessels as a result of the inflammation, and the gallbladder is completely destroyed. Such a condition is illustrated in Case 4. The patients frequently suffer with more or less constant excruciating pain, requiring morphin for relief. Often the condition is mistaken for pancreatic necrosis in association with cholecystitis. In such cases, however, there will be more shock and inability to control the attack, which terminates fatally within a few days. If the patient has a gangrenous gallbladder without pancreatic necrosis, there is usually not the same evidence of shock and general reaction. Most of these patients recover. However, it is my opinion that unless there are some definite contraindications, such black, necrotic gallbladders should be removed rather than drained:

Case 4 (A441154). Dr. S., a man, aged forty-six years, had had one mild attack of colicky epigastric pain, three months before coming to the Clinic, and one week before, a more severe attack, followed by residual soreness and toxemia. The temperature was 101°; soreness and some pain persisted.

At examination the right upper quadrant was very tender. The gallbladder was palpable and distended. There was a tinge of jaundice. The temperature was 98.6°. The leukocytes numbered 22,000. Operation was advised. The patient was kept in bed for five days. The temperature was 101°, but gradually subsided. The leukocyte count decreased to 10,100.

Operation was performed September 14, 1923, twelve days after the onset of the last attack. The gallbladder was found to be distended and gangrenous, the mucous membrane black, and stones were impacted in the cystic duct.

Cholecystectomy was performed. One split tube with gauze and one gauze pack were inserted. The drains were removed on the ninth and eleventh days. Convalescence was uneventful.

RECURRENCE OF CALCULI IN THE GALLBLADDER

Another problem which has been widely discussed is the recurrence of stones in the gallbladder after cholecystostomy. Although cholecystostomy is satisfactory in the majority of cases, symptoms continue to recur in too many instances to warrant its performance except in special cases. Usually the symptoms in these cases are due to the continuance of the infection in the gallbladder, or to the secondary formation of stones. Case 5 illustrates this point. Secondary removal of the gallbladder has been necessary in so many instances as to indicate primary cholecystectomy in most cases.

Case 5 (A56171). Mrs. G., aged fifty-two years. In 1911 the patient had had a cholecystostomy to relieve gallstone colic which had persisted for twelve years. Four years later, following a severe infection in her hand, the colics returned, and recurred about once a month, until the time of her admission to the Clinic. She had not had jaundice.

September 27, 1923, cholecystectomy without drainage was performed. The gallbladder was contracted and destroyed; one stone was impacted in its neck, but there were no other calculi. Convalescence was uneventful, and the patient was dismissed from the hospital on the sixteenth day.

COMMON DUCT STONE

When the common duct is involved in an inflammatory process or contains stones, a much more serious problem is presented. There is interference with the flow of bile into the intestine, usually resulting in jaundice. Common duct stone is distinguished from carcinoma of the ampulla, obstructive pancreatitis and other obstructing inflammatory conditions by interval attacks over a period of years, associated with more or less jaundice, which clears up in the interim between attacks. If the obstructing lesion is a neoplasm, the jaundice is usually painless and gradually deepens, although it may fluctuate from time to time. However, we must always bear in mind that some cases of common duct stone have associated painless jaundice, and that unless there is some definite contra-indication, an exploration should be made to determine definitely what the condition is. Most patients with common duct stone will get well, whether they are operated on during the interval between the attacks, when the jaundice is subsiding, or during the attack. In Case 6 the patient was allowed to go

home, because his jaundice seemed to be subsiding; the plan was to operate when the jaundice had disappeared. However, he returned in a few days much more deeply jaundiced, having had another attack, and it was necessary to perform the operation without further delay. Generally it is best to carry the patient along until he is as free from jaundice as possible. As a rule it is better not to remove the gallbladder from a jaundiced patient, but to drain it and the common duct separately after the removal of the calculi. Removal of the gallbladder during the stage when biliary cirrhosis is present sometimes leaves an oozing surface, difficult to control by suture, and necessitating gauze packing. Bleeding may occur when the pack is removed, and serious results follow. Furthermore, the gallbladder is nearly always completely destroyed and its removal later may not be necessary.

Case 6 (A445588). W. Z., a man, aged fifty-three years, had had a sudden severe epigastric colic, characteristic of that observed in association with gallstones, a year and a half before coming to the Clinic. Vomiting had been associated. One year later, painless jaundice occurred, and persisted, with the exception of a few short remissions. Chills and sweating had occurred almost every month, with deepening of the jaundice after the chills.

At examination, the patient was jaundiced, and had lost 25 pounds in weight. There were no other significant findings.

The patient returned home to have treatment with calcium lactate, but came back three weeks later with somewhat more marked jaundice and a coagulation time of ten minutes; it had been four minutes at the time of his first examination.

November 28, 1923, cholecystostomy and choledochostomy were performed. The gallbladder was destroyed and filled with stones. Stones were impacted in the ducts, several being removed from the hepatic ducts. One large Robson drain and one Penrose drain were used. The patient was dismissed on the twenty-fourth day with his wound healed, general condition improved, sclera white, and bowel movements dark.

COMMON DUCT STONE AFTER CHOLECYSTECTOMY

It has been suggested that the common duct is more prone to be the seat of stone formation after the removal of the gallbladder. This hypothesis was based on the assumption that the common duct would take up the function of concentrating the bile which the gallbladder had performed, but apparently this does not occur. Recently we sent follow-up letters to one hundred patients whose gallbladders had been removed more than twenty years before, and in a study of this series we have found only one instance in which there was reason

to believe that stone had formed in the common duct after the cholecystectomy. Case 7 is one in which stone was found in the common duct after removal of the gallbladder. It would be entirely possible to overlook stones at the primary operation, and it seems probable that these stones were in the ducts at the time of the cholecystectomy:

Case 7 (A439983). C. O., a man, aged fifty-six years. Because of colic and jaundice, the patient had had his gallbladder removed five years before coming to the Clinic. The jaundice cleared up within a year, but during that time he had had an operation for adhesions. Following this, he remained well until three months before admission, when he had chills, nausea, and jaundice, but no pain.

At examination, he was moderately jaundiced, with bile 3 on a scale of 4, in the urine. His coagulation time was twelve minutes, but this was reduced to five and one-half minutes by three injections of calcium.

At operation, September 11, 1923, multiple stones were found in the common duct, one in the left hepatic, and one lodged at the ampulla. The stones were removed with a scoop, and a Mayo-Robson drain inserted. The drain was removed on the eleventh day. The stools on the fifteenth day were greenish. The patient left the hospital on the twenty-third day, and was dismissed from the Clinic on the thirty-fifth day. The jaundice had almost entirely disappeared, the stools were dark, and the wound had healed. A letter received recently states that the patient has continued to improve.

In Case 8 it is definitely known that stones were present in the gallbladder at the time of the cholecystectomy which had been performed twelve years before. The patient was well for seven years before the occurrence of any further symptoms, and there had been no jaundice, chills, or fever at any time since the cholecystectomy, which could be explained by the fact that the stone which we found at the second operation was so small that it had not caused complete obstruction of the duct, although it was of sufficient size to produce typical symptoms. This may be a case in which the stone formed after the removal of the gallbladder:

Case 8 (A445943). Mrs. H. E., aged fifty years, came to the Clinic in November, 1923. In 1911, she had had cholecystectomy for typical gallstone colic, and stones were found. She was well up to 1918, but since then had had attacks similar to those before operation, coming on at first at long intervals, but later, once or twice a week. The pain was colicky, requiring hypodermics, and radiating to the back. There had been no jaundice, chills, fever, or rise in temperature at any time.

The physical examination was essentially negative. November 22, 1923, choledochostomy was performed, and a small stone removed from the common duct. The liver and pancreas were grossly normal. The discharge from the wound stopped on the thirteenth day, and the drain was

removed. The patient was dismissed on the twenty-fourth day in good condition.

CHOLANGITIS AFTER CHOLECYSTECTOMY

We have been much interested in a group of cases in which there was a continuance or recurrence of symptoms after cholecystectomy, and in which we operated expecting to find common duct stones, but were disappointed. All of the patients had had typical gallstone colics from three months to seven years after cholecystectomy. Jaundice was not a common symptom, and in no case was it deep. At the secondary operation we found the common duct dilated as is usual following cholecystectomy, whether stones are present or not. We opened and explored the ducts, passing probes and scoops up into the hepatic ducts and down through the common duct into the duodenum, but no stones were found. About four-fifths of the patients were relieved of their symptoms, whether from cholangitis, hepatitis, or pancreatitis, by secondary drainage of the liver ducts; however, it does not seem that this procedure is warranted at the time of cholecystectomy, as only a very small percentage of patients have sufficient trouble of this kind to warrant secondary operation.

Case 9 (A145261). Mrs. W. H., aged forty-seven years, came to the Clinic in October, 1923. In 1916, she had had a cholecystectomy for a strawberry gallbladder containing one stone. She was well until 1921, when she had a sudden chill, temperature 104°, and severe upper abdominal pain requiring hypodermics for relief. There was no jaundice. Since then, she had had intermittent attacks, about three months apart, consisting of severe pain, vomiting, chills, and fever. On one occasion only was there any jaundice. After some of the attacks, the patient had night sweats for one or two weeks.

The examination was essentially negative. At operation, October 24, 1923, the common duct was four or five times normal size. I had difficulty in introducing a probe, but succeeded in getting a hemostat through, and then a large scoop, but no stones could be demonstrated. A Mayo-Robson drain was inserted and left in place seventeen days, until drainage ceased. The patient was dismissed on the twenty-second day, with stools and skin normal.

CHOLANGITIS

Another group of cases, in which cholangitis seems to be the chief cause of the patient's complaint, presents a serious problem. Case 10 is representative of this type. Following cholecystectomy and drainage of the ducts, the patient was relieved for only three months. Then secondary drainage of the duct was established for three months, but this has not afforded relief, and at the

present time the patient is suffering from attacks similar to the original ones, consisting of chills, with a rise in temperature, but no pain or jaundice. Some of these patients undoubtedly should have long-continued drainage of the liver ducts by means of the Deaver T-tube, and if this particular patient returns, this treatment will be instituted.

Case 10 (A418277). C. P., a man, aged fifty-seven years, came to the Clinic in February, 1923. A few years before he had had a typical gallstone colic with jaundice, but after that remained well until 1920, when he again had epigastric colic, chills, fever and jaundice. A similar attack occurred in 1921, and another in 1922. The latter was not definitely colicky. During the last year the patient had had several attacks of malaise, chills, and fever, without colic or jaundice. Calomel gave definite relief.

At examination the liver was enlarged, but there was no jaundice. Examinations of the urine and blood were negative.

At operation, February 23, 1923, cholecystitis with cholelithiasis and associated cholangitis were evident. The common duct was dilated, but no stones could be demonstrated in it. Cholecystectomy and choledochostomy were performed. One Mayo-Robson drain was stitched into the hepatic duct. The patient was dismissed on the thirty-first day, with the wound completely healed. He went home and was free from trouble for three months. He then began to have attacks similar to those previously experienced, with a sudden rise in temperature to 103°. There were no chills. These attacks occurred weekly, lasted about three days, and were apparently checked by calomel. Smears and repeated blood cultures were negative. Quinin had no beneficial effect.

September 7, 1923, a Mayo-Robson drain was inserted into the common duct for prolonged drainage. Marked pancreatitis and hepatitis were present. The common duct was enlarged, but no obstruction was demonstrable. The patient improved, and returned home, wearing the drainage tube, which ceased to drain, or drained only intermittently, after two months, and was removed. December 30, he wrote that he had had a recurrent attack of fever lasting three days.

HEMOLYTIC ICTERUS AND GALLSTONES

Gallstones may be present without being a factor in the production of jaundice. It is always well to bear this fact in mind and remember that the patient may have hemolytic jaundice. Although there may be some relation between the existing cholecystitis and the biliary condition that attends it, removal of the gallbladder will not clear up the jaundice. The distinction between hemolytic and obstructive jaundice can be made by a careful study of the clinical history. In the former, there is usually a family history of jaundice, or the jaundice has existed since childhood. Furthermore, there is little if any bile in the urine, and the examination of the blood will show an increase in the

fragility of the red cells. The spleen is usually large and can be palpated. Treatment in these cases should consist of splenectomy, and removal of the gallbladder at the same time or shortly afterward; an operation for only one of the two conditions will not be sufficient.

Case 11 (A310506). A. R. M., a single man, aged thirty-one years, had been somewhat yellow as a child. There was no family history of jaundice. He had had severe attacks of epigastric distress when he was five years old, during an illness which was diagnosed pneumonia. The attacks recurred and had become more numerous during the last eight years. He was markedly jaundiced immediately after an attack, and slightly jaundiced between attacks.

At examination the patient was slightly jaundiced. There was no bile in the urine. The spleen was palpable. The hemoglobin was 75 per cent; erythrocytes numbered 4,430,000. There was moderately increased fragility of the erythrocytes. The x-ray revealed a diseased gallbladder containing stones.

At operation, November 19, 1923, the spleen was three times normal size (185 gm.), and was removed. There was moderate fibrosis and destruction of the malpighian bodies. The gallbladder was filled with stones, but it seemed best to postpone further operative procedure. November 30, cholecystectomy and appendectomy were performed. The gallbladder contained many stones, was thickened and inflamed. A marked hepatitis was present. The appendix was obliterated throughout.

WHITE BILE

It was formerly supposed that the presence of white bile in the common duct indicated that the liver function was entirely suspended, and that the case would terminate fatally, but investigations recently carried on at the Rockefeller Institute show that this colorless fluid in the common duct is not bile, but is secreted by the walls of the common duct under sufficient pressure to hold the bile back in the liver. Within a few hours after the duct is opened and drained, in most instances, the drainage changes and normal-appearing bile is seen. It is not known why we do not find this clear colorless fluid in all cases in which the common duct is completely obstructed. Experimental work has shown that if the common duct is ligated below the entrance of the cystic duct, so that the gallbladder retains its communication with the biliary tract, this white fluid is not secreted. In certain cases in which the gallbladder is out of commission, and complete obstruction of the common duct by stricture is suspected, a slight amount of bile may pass through the strictured area, and thus explain the absence of the colorless fluid. According to our observations in these cases of so-called white

bile in the common duct, the results of operations on the common duct are just as satisfactory as in any of the deeply jaundiced patients. In Case 12 there was a quantity of this clear fluid in the biliary ducts at the time of operation:

Case 12 (A294436). Mrs. C. C., aged forty-three years, came to the Clinic in October, 1919. She had had gallbladder disease since 1903, and cholecystectomy had been performed in August, 1918. Two months later, persistent jaundice had developed. She had lost 25 pounds in fourteen months.

At examination jaundice was marked, and bile 2 was found in the urine.

November 4, 1919, hepaticoduodenostomy was performed. There was complete obstruction of the hepatic duct at the site of the cystic duct. There was no bile in the ducts, but 200 c.c. of clear fluid were found. The pancreas was normal. On the sixth day after operation there was slight drainage of bile from the wound, but none thereafter.

Convalescence was uneventful, and the patient was able to leave the hospital on the seventeenth day, with the wound practically healed, and the jaundice subsiding rapidly. In a recent letter, the patient writes that for two years after the operation she was in excellent health, but since then has had attacks of colicky abdominal pain at intervals of from two to eight weeks, very similar to those which she experienced before the removal of the gallbladder, in 1918.

STRICTURE OF THE COMMON DUCT AFTER CHOLECYSTECTOMY

One of the most serious complications we have to contend with in surgery of the biliary tract is the occurrence of stricture in the common duct after cholecystectomy. Undoubtedly some of these strictures result from technical errors; in other cases, however, it is impossible to determine just why stricture occurred, as the patients seem to have been entirely well for a number of months after the gallbladder was removed. During this time the bile apparently passed normally down the duct, and then without any known cause a painless jaundice developed. In certain instances as much as nine to twelve months elapsed without any indication that the lumen of the duct was not entirely normal. In some of these it seems possible that a hematoma formed, or that as a result of packing with gauze or a large drain, sufficient scar tissue may have developed to cause stricturing of the duct when the tissue had contracted. I am inclined to believe that since we are closing the wounds in more of these cases with little or no drainage, we have seen fewer cases with this very serious sequence.

Case 13 (A451152). Mrs. S. B., aged fifty-five years, came to the Clinic in January, 1924. She had had a chole-

cystostomy in 1913 without relief of symptoms. Following cholecystectomy, in 1921, her condition was improved for about one year, then there followed nine months of indigestion and some pain. During the last three months, she had had four or five attacks of sudden onset and great severity, requiring morphin. Chills and some fever were associated with these attacks. The patient was not free from jaundice at any time during these three months.

At examination, a small mass was palpated in the right upper quadrant. The patient was deeply jaundiced. The coagulation time was ten minutes.

Operation was performed January 2, 1924, after pre-operative preparation with calcium. The patient had biliary cirrhosis from stricture of the common duct following cholecystectomy. A small stone was found in the common duct above the stricture, and calculi were present in the hepatic ducts. The duodenum was opened at a point about 3.75 cm. below the pylorus, and a rubber tube passed into the opening, and also into the hepatic duct; the duct was then anastomosed to the duodenum over the tube.

MALIGNANCY IN THE BILIARY TRACT

Fortunately malignancy of the gallbladder is rare. When it does occur, stones are always found in association with the condition. It is sometimes difficult to distinguish between cancer of the fundus of the gallbladder and empyema with thickened walls and necrosis. Occasionally an operation may be well under way before it is realized that malignancy is present. Because of the rich lymphatic circulation between the gallbladder and the liver it is hardly conceivable that malignancy could exist in the gallbladder for any length of time without extension into the liver. Moreover, radical operations for cancer of the fundus of the gallbladder have not been very successful, probably because of this rich network of lymphatics. A case of cancer of the gallbladder with cholelithiasis (Case 14), and one of primary cancer of the cystic duct (Case 15) are reported:

Case 14 (A59903). Mrs. E. F. G., a woman, aged sixty years, came to the Clinic in August, 1923. She had had mild epigastric cramps for two years, and an attack of severe colic two weeks before examination. Three days after the attack, a lump was discovered in the region of the gallbladder. She had lost 10 pounds in weight in the last six months.

At examination, there was a mass in the region of the gallbladder. There were no other significant findings.

August 7, 1923, cholecystectomy was performed. Acute cystic cholecystitis was present, and cholelithiasis. A large cancer was found in the fundus of the gallbladder. A nodule was removed from the liver, and was reported "inflammatory" by the pathologist. Following operation, pleurisy with effusion developed, and a small quantity of fluid was aspirated. The patient was dismissed on the twenty-eighth day. She returned to the Clinic October 24, 1923, to be checked up on account of her fear of a return

of the malignancy. She was in good condition, felt well, and had an excellent appetite.

Case 15 (A446388). E. B., a man, aged fifty-six years, came to the Clinic in November, 1923. Two years before, he had had a sudden attack of colicky pain in the right upper abdomen, without nausea, vomiting, or fever. Several similar attacks followed, in some instances requiring morphin. Then the patient was well until three weeks before coming to the Clinic, when he had an attack of aching pain in the upper abdomen. At this time his home physician discovered a movable mass. The patient had lost 18 pounds in weight.

At examination, the hemoglobin was 73; the urine, normal. The phenolsulphonephthalein test gave a 60 per cent return. Roentgenograms of the bladder, ureters, and kidneys were negative, as were also the cystograms and pyelograms.

Operation was performed November 9, 1923. The palpable mass was found to be a large hydrops of the gallbladder. At the distal end of the cystic duct there was a mass 2.5 cm. in diameter, hard, indurated and intimately attached to the surface of the liver. This mass and the intact gallbladder were removed. The gallbladder contained about 300 c.c. of pus, mucus, and stones. An ulcerated carcinoma with a large gallstone firmly fixed in the center, involved about 1 cm. of the mucosa of the cystic duct. Two Penrose drains were used and were removed on the sixth and eleventh days, respectively. Convalescence was uneventful. The patient was dismissed on the eighteenth day after operation, with the wound healed.

This is the only case of primary cancer of the cystic duct that I have seen. The gallbladder was large and distended, and there were stones in it. The cancer in the duct was rather small and had not invaded the common duct; hence there was no jaundice. However, the growth was attached to the liver, and while removal was apparently satisfactory, I am afraid the ultimate results may be influenced by the fact that some of the lymphatics of the liver may be involved.

CONCLUSIONS

In conclusion I wish to emphasize the fact that the results of operations for inflammations in the biliary tract are, as a rule, very gratifying. The gallbladder may be removed, stones taken from the common duct and the biliary tract drained, and the individual return to a normal state of health in a short time with very slight prospect of ever having any further trouble.

The case histories which I have given here, tonight are those of patients who have presented definite problems. It is through the study of groups of cases of this kind that we hope to be able to overcome our difficulties and make still further progress in the treatment of these patients.

DISCUSSION

DR. STRACHAUER: Dr. Judd has certainly very successfully staged an old-fashioned "hard time party," and, of course, it is from the mistakes and unsuccessful cases that we learn and profit. It surely must be understood, however, that the cases he has presented form a very small percentage and that the great majority of cases which have had a cholecystectomy performed have been successful and satisfactory and have had no occasion to return to Rochester or elsewhere.

The consideration of cholecystectomy versus cholecystostomy always comes up in the discussion of the subject of cholecystitis. My personal experience goes back not alone to the time when cholecystostomy was invariably performed, but to the time when it was considered desirable to suture the gallbladder to the parietal peritoneum. Some of the acute cases were sutured to the peritoneum and left for several days for adhesions to form before opening the gallbladder.

The results of cholecystectomy are so much more satisfactory than from cholecystostomy that there is no comparison. Even the laity have become educated to this fact, and I have had a number of patients, requiring gallbladder surgery, tell me that they wanted me to be sure to remove the gallbladder, citing the experience of some friend or relative who had had the gallbladder "only drained" without satisfaction and that later removal of the organ was necessary.

Cholecystostomy, when performed, except in the aged, debilitated and nephritic, should be done as the first step in a two-stage operation, the second stage being a cholecystectomy, and the acuteness of the infection in the gallbladder at the first operation being such as to contraindicate the immediate removal of the organ.

Regarding the acutely inflamed gallbladder I wish to particularly stress the following: As far as I am personally concerned I have never had nor seen one case of acute cholecystitis die without operation. The mortality chapter—the dark chapter—in surgery of the gallbladder has to do with acute cholecystitis. The situation is not comparable to acute appendicitis. The acutely inflamed appendix and the gangrenous appendix are prone to undergo rupture and perforation, and, of course, the diagnosis of acute appendicitis carries with it the indication for a prompt operation. Not so the acutely inflamed gallbladder. In my entire University Hospital experience and private practice I have seen only two cases of rupture of the gallbladder. In one of these the abscess was well walled off by the omentum and surrounding structures, and the patient, a man 79 years of age, was walking about the city of Minneapolis in comparative comfort. Both of these patients got well. We all know that operation on the acutely inflamed gallbladder is an extremely dangerous one. In removing the organ we open up a raw area of the liver which bleeds freely and offers an inviting avenue for the extension of the infection. Post-operatively the liver function is interfered with and acidosis develops. If these acutely inflamed gallbladders are operated upon, cholecystostomy as a first-stage operation should be performed. Personally, I put the patient to bed, in a hospital, on liquid

diet, with morphin to inhibit peristalsis, and avoid catharsis. Daily leucocyte count is made, and under this regime no case developed surgical complications nor required emergency operation. When the acute phase of the infection has subsided and the patient is taking fluids generously, eating and sleeping well, I go in and remove the gallbladder. The extra-hazard has passed and the patient can be safely operated upon. Bevan, among others, is one of the outstanding exponents of this practice of waiting for the favorable stage before operating and not unnecessarily exposing the patient to this avoidable danger.

It is extremely important to avoid the use of the cigarette or gauze drain, as the latter undoubtedly are responsible for inflammatory stricture of the common duct and adhesions in the neighborhood. I am confident that our increasing ability to close these cases without drainage will result in the elimination of a definite number of unsatisfactory post-operative results.

Dr. Judd called attention to the work of Graham and his associates on the relation of hepatitis to cholecystitis. Dr. Judd's slides show only the advanced degrees of hepatitis. By routinely taking a section of the liver for microscopic examination it is surprising how frequently a seemingly normal liver will show round-cell infiltration, indicating hepatitis. Dr. Graham believes that the route of infection to the gallbladder is by way of the portal vein to the liver and by way of the lymphatic communication between the liver and gallbladder to the latter organ. While this route of infection has not been absolutely proven, there is no question about the intimate relationship between the liver and the gallbladder, and the infection at various times, in all probability, travels both ways back and forth between the liver and gallbladder. The removal of the gallbladder breaks this vicious circle, and the illustrations shown by Dr. Judd this evening, in my opinion, emphasize the importance of an early removal of the gallbladder so as to prevent the increasing degree of hepatitis.

Surgeons are regularly confronted with the difficulty of establishing the diagnosis of chronic cholecystitis even when they can see and palpate the gallbladder at the time of operation. The color of the organ, the subserous deposit of fat, the thickness of the wall, the condition of the regional lymphnodes and presence of adhesions are, of course, all to be taken into consideration. Positive evidence at times, however, is absent in a case with a positive history of gallbladder disease. I wish to offer as a diagnostic procedure at the time of operation the removal of a section of the liver for immediate frozen section examination, and suggest that in the presence of round-cell infiltration the gallbladder be removed.

In conclusion, as a matter of passing interest I wish to cite the case of Professor Barker, of Baltimore, who, when 8 years of age, had typhoid fever; 35 years later, at the age of 43, he was operated upon for gallstones. Professor Chas. R. Austrian, bacteriologist at Johns Hopkins, grew a pure culture of typhoid bacilli from the gallstones, and there had been no repetition of the typhoid infection since the age of eight.

DR. A. E. WILCOX: The problems of gallbladder surgery have been most excellently exhibited in the cases shown

by Dr. Judd this evening. The difficulties encountered in determining real pathology from the gross appearance in the biliary area have been emphasized, and Dr. Judd's opening remarks emphasize one point which has always been a problem to me. That is, frequently we have a typical syndrome, and we are sure our diagnosis is correct, that is, cholecystitis or gallstones with positive indications for operative procedure, but upon opening the abdomen we find what appears to be a normal gallbladder, no stones are palpable and not a definite gross excuse for excision. In these cases we may find an accompanying diseased appendix, upon removal of which all symptoms cease. Yet, on the other hand, we periodically find that symptoms persist, and we are in a quandary as to what the real cause of the trouble is.

To state that the gallbladder is normal is a difficult problem. I am not sure that I know what a normal gallbladder looks like, or at least I am satisfied that a normal appearing gallbladder is very deceptive.

I believe that the clinical syndrome sufficient to make a diagnosis is sufficient indication for excision of the gallbladder providing the appendix shows no pathology. However, it is a matter of surgical judgment in each individual case as to just what will be done when the abdomen is opened in this type of case.

I have had excellent results since I have been encouraged to close some of these abdomens without drainage, and I feel a great step forward has been made by so doing.

The question of hepatitis, cholangitis, and pancreatitis are still problems to be solved and involvement of the common duct not only requires unusual surgical skill but rare judgment as well in determining between cholecystectomy or drainage of the gallbladder in conjunction with drainage of the common duct.

Dr. Judd's paper, as usual, has been extremely instructive, and his results are very consoling to those of us who meet these problems occasionally. We are deeply indebted to him for this interesting paper, and the society is to be congratulated upon having provided for its presentation.

DR. A. L. CAMERON: (Requested to cite his case which had been previously reported.) My case concerned a man thirty-two years of age whose history was quite typical of recurring attacks of cholecystitis without jaundice over a period of three years. At the time of operation the gallbladder was found to be greatly distended and tense. Upon palpation the cystic, hepatic and common ducts appeared normal. The gallbladder appeared quite acutely inflamed, and for that reason it was decided best to drain it. It was opened at the fundus and completely evacuated of a mucoid, colorless material.

Following this, normal looking bile flowed freely to the exterior. Evidently an obstruction had obtained in the cystic duct, presumably a mucous plug.

With my finger inside the gallbladder I determined definitely that no stones were present. The gallbladder wall was very thin and due to the absence of adhesions was readily palpated throughout. The gallbladder was drained.

Eighty-six days later, following several attacks of right upper abdominal quadrant pain the patient was again operated upon. At this time the gallbladder was found to be shriveled up, thick walled and full of stones. These

calculi without doubt had formed subsequently to the first operation.

DR. WILLARD D. WHITE: I was much interested in that part of Dr. Judd's paper which told about these cases where he got a pretty definite history making you think you had pathology in the gallbladder and then, when the gallbladder was opened, very little was to be seen pathologically. I was interested in that especially because I have seen cases where I think a definite mistake has been made because the history showed the attacks to have been quite severe. Some cases may require morphin. They may or may not vomit, may or may not have a slight rise in temperature, but usually do not. In this particular type of case you will find very often that the patient has been using cathartics very frequently over a long period of time so that he will get a definite bowel distress, which may very easily be confused with gallbladder distress. I think that one point in the early diagnosis is, as Dr. Judd mentioned in one case, that the distress would shift about. We all know from our physiology, if we stop to remember it, that the content of the bowel is fluid in the cecum and that as the material moves around more slowly it gets more and more hard and dry; so, in some of the cases, palpation of the abdomen will show that the content of the descending portion is fluid, whereas, normally, it is not fluid. Another point in diagnosis is trying to put the patient on accurate bowel management, to have him on such diet that the bowels will move without taking cathartics. In this way a lot of patients who have these attacks will have their supposed gallbladder trouble clear up. They will have so much distress with an attack that they will be afraid to eat large meals, or it may be that they will find that greasy foods are causing their distress, which is considered a point in favor of their having disease in the gallbladder. In these types of cases I think the thing to do is to put the patient on accurate bowel management and get the bowels working without taking cathartics. If they clear up it speaks against gallbladder disease. Of course, there are other things to take into consideration, such as the leucocyte count and temperature; but many of these bowel cases may have a slight rise in leucocyte count and this may help to confuse one. I have seen gallbladders after they have been removed and have heard the surgeon say, "I expected to find definite pathology in this gallbladder as the patient had a fairly definite history of gallbladder disease." Then, when you have asked him about the patient's bowel history, use of cathartics, etc., he will admit he knows nothing about it, having apparently not inquired into this part of the history. In some cases, when you go back and inquire from the patient, you will get a history of long-continued and frequent use of cathartics. At least some of these patients have their distress from an irritable bowel resulting from the use of cathartics and enemas. These, I believe, are the type of patients who, having been operated upon, will say sometime afterwards that they are having their old gallbladder distress, even though their gallbladders have been removed. It is admitted that many of the patients with gallbladder distress will have used cathartics and that their distress may be due to their gallbladders, even though they have used cathartics, but my point is that many of them have their distress from the abuse of cathartics and

enemas and that, therefore, the attempt should be made to establish that fact and avoid unnecessary and, consequently, disappointing operation.

DR. H. B. SWEETSER: The last statement made by Dr. Cameron as to the time of formation of new stones in the gallbladder is open to some question. It reminds me of a patient I operated on some years ago. He had acute cholecystitis with stones. The gallbladder was emptied of stones and drained. A few days later he died. At the autopsy stones were found in the hepatic duct and far up in the ducts of both lobes of the liver. It is easy to imagine that some of these stones could have reached the gallbladder if the patient had lived, and we might have interpreted their presence as an example of new stone formation.

Dr. Strachauer has said he has never seen a case of acute cholecystitis die, and that operation should be deferred till the acute symptoms have subsided. I have seen them die. Only last September, my chum in the medical school died following rupture of his gallbladder. He was taken suddenly sick on a Sunday with acute inflammation of the gallbladder, and was so sick that operation was postponed to allow of subsidence of the acute symptoms. The following two days he appeared better, but on Wednesday the gallbladder ruptured and on Saturday he was dead, notwithstanding a late operation. I cannot understand why we should continue the old idea that there is more danger in operating during the acute stage than in waiting. Years ago the same positive statements of increased danger were made during discussions as to the safest time to operate in acute appendicitis, but no one now delays operation in this disease. I am sure that my gallbladder cases with fever and a high leucocyte count stand a better chance from early operation than from procrastination. When the gallbladder is exposed, one may then decide whether to excise it or be content with simple drainage.

I was very glad to hear Dr. Judd's case of jaundice due to stricture of the bile duct, in which he was sure no injury had been done to the duct at the time of operation, since bile was present in the stools at first. I had a very similar case which caused me much worry. My patient also passed normal colored stools for a few days, followed by jaundice which deepened and with clay colored stools. Later I made an anastomosis between the common duct above the stricture and the duodenum. I also am sure the duct was not injured at the operation.

This has been a very enlightening and instructive paper which Dr. Judd has presented, the more so from the fact that he has elected to tell us of some of his discomfiting experiences rather than of his many successes.

DR. R. E. FARR: I have enjoyed the paper and the discussion very much. I wish to call attention to a number of points and to especially stress some that have been made. I am glad to find surgeons changing their attitude toward the blind abdominal exploration. I have insisted for years that pathology which could be detected by this method could almost always be anticipated by a well-taken history, a good physical examination and properly correlated laboratory data. I recently heard Drs. Crile, Deaver and W. J. Mayo state that they had frequently removed gallbladders which contained stones they were unable to palpate.

The next point I want to mention relates to what we have termed the physiological test. We believe we have proven in a comparatively large number of cases that it is possible to reproduce the patient's pre-operative symptoms by squeezing or making traction upon the suspected viscus, i. e., gallbladder, appendix, ovary, et cetera, in the patient. Lowen has, by blocking the nerves supplying the appendix or gallbladder, been able to relieve the patient's pain, thus receiving great aid in diagnosing between appendicitis and cholecystitis.

Dr. Judd in his message tonight has called attention to what might be called "freak" cases. It must be from a large series of gallbladder cases that so many unusual conditions have been found. I have had considerable trouble in some of my gallbladder work, but it has been as a rule most satisfactory.

I agree with Dr. Sweetser that it is entirely possible that the gallstones found in Dr. Cameron's case formed in one of the hepatic ducts and were present when he opened the gallbladder the first time. I have in a number of instances, after completely emptying the gallbladder and draining it, found a number of gallstones upon the dressings after the removal of the tube. I would like to ask Dr. Judd if he has not had the same experience. I do not see that Drs. Cameron and Strahauer have proven their point that these gallstones formed during the period between his first and second operation. In relation to the length of time it takes gallstones to form I had an opportunity to make an important observation. Many years ago, while taking care of a man for typhoid fever he developed an acute attack of cholecystitis. He afterwards insisted that this was his first attack. Ninety days after the onset of this attack I performed a cholecystostomy upon him on account of recurrent colics. As the gallbladder was sponged out with gauze numerous small gallstones were removed. From these pure cultures of typhoid bacilli were obtained. As he had never had typhoid fever before it seemed reasonable to assume these stones had been ninety days in forming. However, if Dr. Cameron's reasoning is correct, the stones in his case were developed four days earlier than in mine.

DR. JUDD, closing: Dr. Strachauer and Dr. Farr have both emphasized one of the points I wished to make in this discussion—that gallbladder surgery, as a rule, is extremely satisfactory.

Each of the cases I presented here tonight illustrated some point about which we are not entirely decided. By studying cases in this way, we should be able to improve our results, though I believe the outcome is satisfactory in 90 per cent of the cases.

Dr. Farr asked me whether I had ever found stones on the dressings in cases where no stones were found at the time of the operation. I have had this experience, and of course, I have always been in a quandary as to what part of the biliary tract the stones came from.

Dr. Cameron's report brought up a most interesting point—the length of time necessary for gallstones to form. When I first heard the report I felt that he had not emphasized the methods and detail of the examination of the gallbladder at the initial investigation. This case suggests the rapidity with which stones may form.

HYPERTENSION IN PREGNANCY*

FRED L. ADAIR, M.D., F.A.C.S.

Associate Professor of Obstetrics and Gynecology,
Medical School, University of Minnesota

Minneapolis

For many years it has been deemed advisable to make routine examinations of the urine during pregnancy. More recently, especially in the last fifteen years, considerable attention has been given to the routine observation of blood pressure during pregnancy. The purpose of these two methods of examination is to detect disease conditions before the mother and her unborn child have been seriously injured by the inroads of disease. The pathologic conditions with which we are particularly concerned are the toxemias of pregnancy. Inasmuch as we are in ignorance of just what these conditions are, we are unable to tell whether we are dealing with one or several disease conditions. We know something of the pathology in the cases which terminate fatally. We know little of the effect of these disease conditions upon the subsequent life of the patient. A careful study of the blood pressure of pregnant women may not only help us to protect the individual from the ravages, but also throw some light on the problem, of the toxemias of pregnancy.

We should guard against the consideration of blood pressure as an isolated condition in any case and especially in pregnant women. We know relatively little of the significance of blood pressure. Hypertension presents many unknown factors and unless extreme or associated with other abnormal conditions its significance in a given case should be determined only after careful scrutiny of other factors in the case. In pregnancy, hypertension is a finding of considerable importance because of its well known association with the toxemias of pregnancy. Much has been written concerning high blood pressure in pregnancy, but aside from showing its almost constant association with the eclamptic toxemias, little has been done to determine the real significance of hypertension during pregnancy.

So far as the literature goes, very little attention was given to blood pressure in pregnancy toxemia prior to 1907. Partridge in articles written in 1903 and 1907 made no mention of the use of blood

*Presented before the annual meeting of the Minnesota State Medical Association, St. Paul, October, 1923.

pressure readings in the diagnosis of this condition. Allen in 1905 quoted Kroenig to the effect that eclampsia is accompanied with high blood pressure. He also quoted Richardson, who estimated the maximum blood pressure in a case of eclampsia at 208. Allen considered it to be an impractical method of diagnosis. He thought digital compression might give some information of value as to the amount of tension.

Vogeler in 1907 reported a series of fifty cases with observations during labor. He considered all cases with a pressure below 100 to be hypotension. The hypertension cases he grouped into moderate, under 180, and extreme, above this figure. Vogeler drew the following conclusions:

1. Normal blood pressure during pregnancy is 100 to 150 mm.
2. The pressure is higher during labor, but any postpartum pressure above 150 mm. or below 90 mm. is abnormal.
3. Hypotension less than 90 mm. indicates hemorrhage.
4. Hypertension above 150 needs watching.
5. Hypertension 150 to 180 is incompatible with completion of full term pregnancy and labor.
6. Marked hypertension over 180 is a grave symptom.
7. Hypertension with convulsions is an absolute indication for emptying the uterus.
8. Marked hypertension persisting in spite of treatment in connection with edema and cerebral symptoms is dangerous even without convulsions. Termination of pregnancy is indicated.

Skeel (1909) thought the normal pressure was about 130 during pregnancy. A pressure of 160 to 180 does not exist in normal pregnancy. He considered the absence of albumen or a trace of albumen to be of no value in determining the existence or non-existence of toxemia. A progressively increasing quantity of albumen indicates trouble. For this reason he believed that blood pressure observations during pregnancy have an increased importance. Digital compression to determine arterial tension is of no value. Any blood pressure in excess of 150 mm. during pregnancy is abnormal. Blood pressure may be somewhat elevated during labor, but should become normal subsequent to labor. Blood pressure is elevated in both eclampsia and pre-eclampsia.

Bailey (1911) considered the average blood pressure in the last weeks of pregnancy to be 118 mm.

A blood pressure rise over 150 mm. requires investigation. In eclampsia blood pressure is about 200. It may be as low as 155. Convulsions are not apt to occur when the blood pressure is lowered by a poor resistance or drugs. He thought treatment should not be directed especially toward the reduction of the blood pressure.

Judd (1912) wrote that hypertension in itself may require treatment. He thought that eclampsia may be foreseen by blood pressure observations. Hypotension may foretell shock or concealed hemorrhage. He believed the gravity of the case may be determined by the height of the blood pressure and the amount of serum albumen and serum globulin in the urine.

Lynch in 1913 analyzed one hundred private cases. He found only 8.2 per cent with a blood pressure between 121 and 145. He quoted Davis' figures of blood pressure readings in sixty cases during the puerperium, of which 25 per cent had a blood pressure between 131 and 140; it was over 140 in 4 per cent of these cases. He found no relationship between the blood pressure and the percentage of albumen. He reported two cases of eclampsia with very slight if any elevation of blood pressure.

Malcolm Donaldson in 1913 found a uniformly high systolic pressure in a series of cases with albuminuria. In toxic cases the blood pressure tends to fall quickly to normal following delivery. He considered a rising blood pressure to be an indication for the termination of pregnancy.

Hirst (1915) considered hypertension to be more significant of late toxemia than urinary or other changes. He believed that the ordinary systolic pressure of eclampsia is 180. In severe cases it is apt to be over 240. The blood pressure is apt to remain high for ten days or more after the disappearance of other symptoms. He advocated the lowering of blood pressure by sweating, purgation, *veratrum viride*, rupture of the membranes, and venesection when it is above 180.

Barnard thought that any blood pressure rise above 140 is abnormal. In his series of 200 cases, 18 had a pressure of 140 to 225. All of these cases had albuminuria. All his eclamptics except one had a marked elevation of pressure. This was 145 until after delivery.

Riesman (1915) was of the opinion that blood pressure readings during pregnancy are of par-

ticular importance. He mentioned three forms of hypertension: (1) associated with nephritis; (2) accompanying arterio-sclerosis; (3) a mysterious form occurring in middle age without apparent renal involvement.

Newell (1915) reported 450 cases. He said that many women show a temporary rise in blood pressure during pregnancy. Five of his patients had a blood pressure of 140 or over. He considered the rise in blood pressure to be an indication of possible toxemia even in the absence of other symptoms. He thought that the age of the patient did not influence the blood pressure during the child-bearing period. He believed that there is a tendency toward an increase of blood pressure with each subsequent pregnancy.

Litzenberg gave an analysis of blood pressure in 524 cases. About 20 per cent had a rise above 130. The diastolic pressures give no more information than the systolic, though a relatively high diastolic pressure may be of significance. About 11 per cent of his cases showed a diastolic pressure above 86. Dr. Litzenberg stated that about 3 per cent of the patients with a systolic pressure between 130 and 140, about 9 per cent of those between 140 and 150, one-third of those between 150 and 160, one-half of those between 160 and 180, and practically all with a pressure over 180, have toxemia. Albuminuria occurred without hypertension in about 31 per cent of his cases, and hypertension without albuminuria in about 46 per cent of them. Irving found hypertension occurring before albuminuria twice as frequently as albuminuria preceding hypertension. Eclampsia may occur without hypertension.

Danforth reported 115 private cases. He thought that the average pressure of the pregnant woman is less than that of the non-pregnant. He believed that labor causes a rise in blood pressure, and that toxemia of pregnancy is accompanied by hypertension except in rare instances.

Warfield (1919) divided hypertension cases into subacute and chronic. He thought that in some individuals it is a normal condition and that it runs in families and may be hereditary. He believed that in itself it is not dangerous and does not represent a pathologic process. He stated that no obstetrician does his full duty if he fails to take blood pressure frequently during the last half of pregnancy. He considered three types of chronic hypertension: (1) the chronic interstitial nephrit-

ic; (2) the essential or hereditary; (3) the arterio-sclerotic. Each of these have different grades and may occur in combination.

Schulze (1920) reported a series of fifty cases from the fourth to the ninth month of pregnancy. He estimated the average pressure to be slightly higher for the latter months of pregnancy. He found that the average of 75 readings at term was 123, of 86 readings in the second stage to be 133, of 104 readings three hours postpartum was 120.

Kosmak in 1922 quoted Zangmeister to the effect that edema of the brain is associated with high blood pressure in eclampsia. He considered that the lowering of the blood pressure by venesection tends to reduce the convulsions, and the tendency to edema and hemorrhage of the brain.

De Snoo (1922) agreed with the theory of Bar that there is a close relationship between high blood pressure and sodium chloride retention. He emphasized the importance of treating his pre-eclamptic and eclamptic cases with a salt-free diet. He divided his hypertension cases into three groups: (1) previously healthy women with normal blood pressure who again become normal after delivery; (2) women with latent or chronic nephritis having hypertension; (3) women with primary hypertension. In *Group I* the cases have sodium chloride retention leading to edema. The long standing retention of sodium chloride leads to albuminuria and hypertension. He considered hypertension to be the most important sign of threatened eclampsia. He quoted cases of eclampsia developing without other signs than hypertension. He knows of no cases of eclampsia without hypertension. In this group of cases the blood pressure returns to normal in about fourteen days. Persistently high blood pressure indicates latent or chronic kidney disease. *Group II* (nephritic). These cases do quite well the first half of pregnancy. Hypertension develops in the second half associated with headache, albuminuria, tendency to bleed, and visual disturbances. According to his view, eclampsia occurs almost exclusively in primiparae and it is not apt to recur. There is a tendency to recur in the nephritic type. In this group the blood pressure drops to its usual level about fourteen days postpartum. *Group III* (primary hypertension). This represents a small group of cases. There is no toxemia in these cases. There is no increase in blood pressure during pregnancy. The pregnancy proceeds without complications.

The hypertension in itself might lead to placental hemorrhage and its premature detachment. Out of 31 women with premature separation of the placenta, 22 had hypertension, 18 of the 22 had normal urine. He stated that the best treatment for hypertension cases is rest and salt-free diet. When the blood pressure returns to normal, even with albuminuria, he thinks the pregnancy may be allowed to continue. Repeated venesection has in his hands been without material result, producing only a temporary drop in pressure. He thinks that every pregnant woman with hypertension even without other symptoms should have rest in the latter months of pregnancy.

It is readily seen from the above review of the literature that blood pressure observations during pregnancy have assumed an importance equal to if not greater than the routine urinary examinations. The almost constant association of hypertension with toxemia is well established. It is also definitely recognized by a few that the so-called eclamptic toxemia is not the only cause of hypertension during pregnancy. The problem of hypertension is difficult to unravel because of the numerous factors which enter into its production. It becomes still more complicated because we may have combinations of conditions operating in individual cases. This is particularly true during pregnancy. A normal healthy woman who is pregnant may develop an eclamptic toxemia with hypertension. A woman with hypertension may become pregnant and go through the period of gestation without complications. She may, however, have an eclamptic toxemia superimposed on her pre-existing hypertension. Another woman with a nephritis and an associated hypertension may pass through pregnancy without serious aggravation of the previously existing condition. She may, however, have an exacerbation of the nephritis or develop an eclamptic toxemia superimposed upon the previously existing nephritis and hypertension. These different possibilities must be considered in evaluating the symptoms and findings in any case. Necessarily the opinion formed regarding the condition or conditions present modifies one's judgment as to the proper course to pursue. It is apparent that the hypertension present at the time of observation cannot be the only factor which influences our decision. Antecedent blood pressure observations are of the greatest assistance and one should never

make a judgment on hypertension alone, especially when only one observation has been made.

In order to clarify somewhat the situation regarding blood pressure observations during pregnancy, I have selected a short series of cases which I wish briefly to report together with their blood pressure curves. These observations are not perfect nor as complete as one might wish, but do, I think, bring out certain points of value. Before, however, proceeding with these individual cases I should like to report the blood pressure findings in a series of 38 cases of eclampsia admitted to the Minneapolis General Hospital. These cases were analyzed by Dr. Collier of the resident staff. Of these cases, about 79% were primiparæ, 21% multiparæ. The average age was 25.7 years. The youngest was 17 and the oldest 45. The average blood pressure on admission was 182 systolic and 110 diastolic. On discharge the average blood pressure was 121 systolic, diastolic 72. Of these patients about 18% had no convulsions; 37% had convulsions before and after delivery; 29% had convulsions before delivery, and 16% after delivery. The average stay of these patients in the hospital was about 19 days. About 79% of the patients lived. About 16% died from eclamptic toxemia, and about 5% died from complications.

Fig. I, Case I.

Graph of blood pressure readings.

We will now proceed to show the blood pressure findings in a few illustrative cases. These cases represent different types and in some the blood pressure findings extend over a period of several years; and perhaps will give an idea of what ultimately happens in these cases, not only

in one pregnancy, but in successive pregnancies. It would be much more valuable, of course, if one could follow these cases with rather complete observations for a considerable portion of their lives, but naturally that is very difficult to accomplish. Some of these records have been compiled not only from my own personal observations, but from the records of other physicians. Most of them are private cases and could, therefore, be followed a little longer and perhaps more closely than those who enter the charity wards of general hospitals.

Case I. Mrs. D. S. Age: 19 years. Para I. Grav. I. She had had headache and abdominal distress of dull type all during pregnancy. She was admitted to the Minneapolis General Hospital on January 27, 1922, and was in the hospital for ten days, being discharged on February 6, 1922.

Diagnosis: Parturition O.D.A. Eclampsia—Puerperium.

She was delivered at 12:50 P. M. on January 27, 1922. Convulsions started at 3:30 P. M. Before delivery the blood pressure was 148/78, and at 3 P. M. it went up to 200/90. Edema showed up after the second stage, at which time there was edema of both ankles. There had been no edema up until this time. There was a rapid rise in blood pressure. She had three convulsions that afternoon.

The urine before delivery showed a faint trace of albumen, no sugar or casts, specific gravity was 1023. After delivery there was a large amount of albumen, no sugar or casts, and the specific gravity was 1020.

numerous casts. The epigastric pain occurred at about 11:30 P. M., at which time she also vomited. At 6 A. M. she had a convulsion which lasted ten minutes. A Caesarean section was done at 11:30 A. M., May 29, 1916, before which time she had had three convulsions. She was delivered of a viable child. A hysterectomy was also done because of numerous fibromyomata. On June 17, 1916, she was still having considerable headache. There was no disturbance of vision. On June 20, 1916, a diagnosis of cystitis was made. She made an uninterrupted recovery. She was seen again in October, 1916, at which time the blood pressure reading was 104/68-78. She was later seen in May, 1917, one year after the birth of the child, at which time she was feeling well. The baby's general condition was also good.

HYPERTENSION DURING PREGNANCY Case of Mrs. R.W.C.

Fig. III, Case III. Graph of blood pressure readings.

Case III. Mrs. R. W. C. Age: 26 years. No acute illnesses. Weight 105 pounds. No hypertension.

She was first seen in 1915, at which time she was a little over two months pregnant. She had marked nausea and vomiting with pyrosis and salivation. About four and one-half months later she developed edema, epigastric distress with hypertension and albuminuria. She was treated expectantly in the hospital and delivered of twins about one month later. Labor was induced and she had convulsive attacks. She made a good recovery.

Over a year later she had another pregnancy, with vomiting and albuminuria, for which she had a therapeutic abortion. Subsequently she developed a pyelitis.

About nine months later she had another pregnancy with hyperemesis, albuminuria, and convulsions in the third month of gestation, for which the uterus was emptied.

Two years later she had another pregnancy with hyperemesis for which a therapeutic abortion was done.

About nine months later she had an appendectomy.

Case IV. Mrs. G. J. B. Age: 34 years. She was first seen in 1914, at which time she was about four months pregnant. She had two previous pregnancies with miscarriages. She had no acute illnesses except a suppurative otitis media two years before. Her physical condition was good, except for an acute attack of appendicitis. She developed an acute tonsillitis and operation was deferred until about two weeks later when an appendectomy was done.

HYPERTENSION DURING PREGNANCY Case of Mrs. L.M.S.

Fig. II, Case II. Graph of blood pressure readings.

Case II. Mrs. L. M. S. Age: 37 years. The patient was first seen in July, 1915. She had had measles in childhood. She consulted me on account of sterility. Her physical condition was good. She next consulted me on November 9, 1915, at which time she was 2½ months pregnant. Early pregnancy was uneventful except for an attack of possible appendicitis in November. She had no headache or edema. She felt well in January, having no headache or edema. There were no untoward symptoms in February. About the ninth month she suddenly developed epigastric pain and edema with hypertension and marked albuminuria and

The urine showed no important findings. She had slight hypertension. She felt well and had no edema until about January 26, 1915. Her hands were somewhat puffed. On February 6, 1915, she had a little headache. There was edema of the hands and feet. On this day she was sent to the hospital. About this time she developed a slight albuminuria with a few hyalin casts. She had very marked edema, and marked eye signs. Fundal examination of the eyes showed no demonstrable lesion. Labor was induced on March 1, 1915. On March 3, 1915, she was delivered of a still-born child. After the delivery the patient was dizzy and had some trouble with vision. The placenta was retained, but came away on the sixth of March, three days after delivery. On the twentieth of March the patient left the hospital, her general condition good, but she had some difficulty of vision.

Case V. Mrs. M. Z. Age: 30 years. Para I. Grav. II. Diagnosis: Parturition O. L. A. Toxemia of pregnancy. Eclampsia of parturition.

She was admitted to the Minneapolis General Hospital on January 6, 1922. She appeared confused. She had three convulsions and considerable edema. The blood pressure at this time was 164/110, and the urine showed a large amount of albumen with a few casts. She was delivered at 3:45 p. m. and at 8:55 p. m. she had another convulsion. She was still irrational the next day and there was a good deal of edema. Two days later she had a severe headache and some edema. Five days after delivery she had a typical eclamptic convulsion. At this time the urine showed a moderate amount of albumen with very many casts both hyalin and granular.

HYPERTENSION DURING PREGNANCY Case of Mrs. G.J.B.

Fig. IV, Case IV. Graph of blood pressure readings.

Case VI. Mrs. C. Age: 23 years. She was admitted to the University Hospital on October 12, 1921, and was discharged December 17, 1921. Diagnosis: Pregnancy abnormal O. L. P. Acute nephritis of pregnancy.

At the time the patient was admitted to the hospital she

was seven months pregnant. She had had no miscarriages. There was no venereal history. She had frequent tonsillitis and quinsy. Upon admittance to the hospital, fluid was found in the abdomen and pleural cavities. There was edema of the hands, feet, ankles, legs, thighs, and face.

HYPERTENSION DURING PREGNANCY Case of Mrs. M.Z.

Fig. V, Case V. Graph of blood pressure readings.

This had been progressive since October 17, 1921. She had albuminuria, headache, blurring and spotting, scotomata, and hypertension. She had felt well until about one week before admission. She was kept under observation for a month, the edema increasing all the time. She was delivered on November 14, 1921, of a living baby, after induction of labor.

When the patient entered the hospital she showed a four plus albumen. This continued four plus until delivery, then there was a large trace and a very large trace. The specific gravity varied from 1.017 to 1.016. There were hyalin and granular casts on admittance, and occasional casts afterward. There were none for several days before delivery.

On March 30, 1923, she was again admitted to the hospital. Diagnosis: Toxemia of pregnancy. There was no nausea or vomiting with this pregnancy. There were no convulsions. The urine showed a large amount of albu-

HYPERTENSION DURING PREGNANCY Case of Mrs. Ch.

Fig. VI, Case VI. Graph of blood pressure readings.

men, carrying from two to three plus. Blood pressure varied from 140 to 180 systolic and 90 to 110 diastolic. Labor was induced at the eighth month and she was delivered of a living infant.

HYPERTENSION DURING PREGNANCY Case of Mrs. R.D.M.

Fig. VII, Case VII. Graph of blood pressure readings.

Case VII. Mrs. R. D. M. Age: 36 years. She was first seen on February the fifteenth, 1916. She had had measles, scarlet fever, and typhoid fever. This was the third pregnancy. The first pregnancy resulted in still-birth after induction of labor for eclamptic toxemia. The second pregnancy resulted in a miscarriage at the third month.

When first seen the patient was in good health. There was little evidence of organic disease. The urine showed nothing of importance. She had some hypertension. She was first seen about the fourth month of pregnancy. About the seventh month she developed considerable edema, but no subjective symptoms. At this time she had plus albumen in the urine. She was sent to the hospital and kept on rest and diet. Labor was induced about ten days later. She was delivered of a viable child. She has been in fairly good health. There have been no subsequent pregnancies.

In 1917 blood chemistry: Nitrogen 32; urea 36; creatinin 1; uric acid 3.1; glucose .079. P. S. P. test was 70% in two hours. Day urine was 726 c.c. sp. gr. 1005 to 1027. Night urine 308 cc., 8 grams of sodium chloride excreted 7.1. Intake of thirteen grams of nitrogen excreted 8.2. The urine showed a faint trace of albumen, and a few hyalin and granular casts. A diagnosis of possible glomerulo-nephritis was made.

In January, 1920, her blood pressure was still high. In November, 1920, her blood pressure was 175/102. She complained of her joints being swollen. In January, 1922, she was feeling quite well. At this time her blood pressure was 164/94.

Case VIII. Mrs. G. B. F. Age: 41 years. Para III. Grav. V. Of the four previous pregnancies, two were somewhat premature, one at term, and one miscarriage. There was no history of toxemia. She had had measles, but no other acute infections.

When first seen on February 10, 1921, she was in the

second month of pregnancy. At this time she had a slight hypertension. Her body weight was 205 pounds. The urine was negative until the six month, at which time there was a faint trace of albumen. The urine never showed more than a trace of albumen, no casts, and only a few pus cells.

She later developed hypertension, had marked edema, some headaches, scotomata, tendency to dyspnea, and stiffness of the joints. She improved very little under rest and diet.

Labor was induced with a Vorhees bag on July the twentieth. She was delivered of a premature viable infant about five hours later. Her subsequent health has been quite good.

Case IX. Mrs. J. B. Age: 38 years. She consulted me on September 14, 1920, because of apparent sterility.

HYPERTENSION DURING PREGNANCY Case of Mrs. G.B.F.

Fig. VIII, Case VIII. Graph of blood pressure readings.

She gave no history of a high blood pressure. She had chicken pox and measles in childhood, flu pneumonia about one year previously. When first seen her physical condition was good. She was next seen about five months later when she was about 2½ months pregnant. At this time she had slight hypertension. Fetal life was felt April the fifteenth. On May the twenty-seventh she was in the hospital under rest and diet with some improvement. Blood chemistry: Bld. sugar .15; creatinin 2.2; urea nitrogen 18.2; uric acid 1.6; alkali reserve 59.7; sodium benzoate 86%. Her weight was about 167 pounds. The urine never showed more than a faint trace of albumen, no casts, and very few pus cells. She had marked edema and some epigastric distress. She left the hospital after two weeks' time. Fetal heart tones were not audible when she left. Her condition while in the hospital improved. She returned to the hospital four days later and was delivered of a macerated fetus. She left the hospital in a good condition on June 23, 1921.

She was again seen on September 9, 1921, at which time her general health was good. At this time her blood pressure was 140/94. In November, 1921, at which time I again saw her, she was feeling quite well. She had noticed some puffiness of the hands. At this time her blood

pressure was 150/90. In November, 1922, her blood pressure reading was 152/98.

Case X. Mrs. E. M. L. Age: 31 years. The patient was first seen on April 14, 1914. She had had measles and was subject to tonsillitis. A diagnosis of pregnancy and exophthalmic goitre was made. This was the first pregnancy. There was no edema, headaches, or blurring. She was seen again on May 12, 1914. At this time there was some shortness of breath, but no headaches or edema. She was again seen on June 15, 1914. At this time there had been some headache the last few days, but no edema or visual disturbance. In August she began to have some dizziness and blurring of vision, but no headaches or edema. In September she had some swelling of the feet, but none of the face. There was some blurring of vision the latter part of the month, and some epigastric distress. Albuminuria appeared about the beginning of the eighth monthly, shortly before delivery. She was delivered on October 12, 1914, of a premature infant, precipitately. She had some trouble with her stomach after the birth of the baby.

She was seen again on May 20, 1920. At this time the blood pressure was 158/98-100. On March 8, 1922, she was again seen, at which time a diagnosis of Bartholinian cyst, cystic ovary, hypertension, and goitre was made. The blood pressure reading was 164/108. She was seen again February 27, 1923, at which time the blood pressure was

three months pregnant. She had had typhoid, pneumonia, scarlet fever, tonsillitis, and attacks of upper abdominal colic with jaundice. She had had high blood pressure for over a year. She also had severe headaches. A diagnosis of pregnancy and arterial hypertension was made at that time. About three months later she developed intense head-

HYPERTENSION DURING PREGNANCY

Case of Mrs. E.M.L.

Fig. X, Case X. Graph of blood pressure readings.

ache, vomiting, puffed facies, marked hypertension, and blurring of vision. On the first of August she had intense headache and vomited some. Her face appeared somewhat puffed, although there was no definite edema. Labor was induced on the fifth of August and she was delivered of a macerated fetus.

When the patient was first seen the urine was negative. On July 31, 1916, there was a four plus albumen, which fell to two plus on September 28, 1916.

She was again seen in 1917 when about two months pregnant. She was delivered about five months later of a male child. With this pregnancy she developed albuminuria, some headache, but no edema or visual disturbance. There was marked hypertension. Subsequent to this pregnancy she had functional kidney tests which were normal. She

Case of Mrs. J.B.

Fig. IX, Case IX. Graph of blood pressure readings.

136-138/102. On March 9, 1923, she was operated and the cyst removed. She made an uneventful recovery and was discharged from the hospital in good condition.

Case XI. Mrs. E. A. C. Age: 25 years. She was first seen on September 30, 1921, at which time she was about $3\frac{1}{2}$ months pregnant. This was the first pregnancy. She had only a faint trace of albumen in the urine. This continued all through pregnancy. She had no edema or headaches. When first seen the blood pressure was 156/80, and about four days before delivery it was 170/110. Labor was induced, and she was delivered of a viable child in March, 1922.

Case XII. Mrs. L. M. C. Age: 34 years. She was first seen on April 21, 1916, at which time she was about

HYPERTENSION DURING PREGNANCY

Case of Mrs. E.C.

Fig. XI, Case XI. Graph of blood pressure readings.

was at Rochester in November, 1917, at which time the blood pressure was 210/138. She had a two plus albumen, a small number of pus cells. Combined phthalein test was 60% in two hours. There was beginning albuminuric retinitis with a few small hemorrhages in the retina. She was advised the removal of the tonsils.

HYPERTENSION DURING PREGNANCY Case of Mrs. L.M.C.

Fig. XII, Case XII. Graph of blood pressure readings.

In October, 1919, Dr. H. L. Ulrich found the blood chemistry to be practically normal. P. S. P. was 48%. The Mosenthal Diet: Day urine, 914 c.c. sp. gr. 1010-1020. Night urine, 690 c.c. sp. gr. 1014. She became much worse in November and entered the hospital in a uremic condition. At this time there were large amounts of albumen and many casts. A urea nitrogen of 82, uric acid 15, creatinin 2.5, blood sugar .33. She was nauseated, vomited, had convulsions, and marked nervousness. Her blood pressure reading at this time was 268/152. She died in November, and partial autopsy showed an arterio-sclerotic kidney.

SUMMARY

1. The routine taking of blood pressure readings is very important in the detection and diagnosis of pathologic conditions, especially eclamptic toxemia, during pregnancy.

2. An increase of blood pressure during pregnancy practically always means the existence and progression of some pathologic condition.

3. The presence of a hypertension during pregnancy is not in itself necessarily a serious condition.

4. The causes underlying a hypertension in pregnancy are usually important and are apt to become aggravated during the pregnancy and with each subsequent pregnancy.

5. There are several groups of cases which present hypertension during pregnancy.

6. Eclamptic hypertension is one group which is characterized by an acute hypertension usually followed by a drop to the normal level following confinement.

7. As above, but followed by a persistent though lessened hypertension.

8. An already existent hypertension which does not increase during pregnancy. This form is unusual and makes a second main group.

9. A third main group with an existent hypertension which increases during pregnancy due to the aggravation of the underlying condition, probably a nephritis. These cases are apt to become progressively worse with each successive pregnancy. In some the blood pressure recedes to its usual level, and in others it remains higher subsequent to delivery.

10. The fourth group might include those cases which have an antecedent hypertension upon which an eclamptic toxemia is superimposed. In these cases the preexisting condition may or may not be aggravated by an eclamptic toxemia. In the former instance the blood pressure remains persistently higher as a rule, and in the latter it resumes its usual level.

DISCUSSION

DR. E. L. GARDNER: Dr. Adair has presented a very interesting and comprehensive paper. Hypertension in pregnancy is one obstetrical subject which is of particular interest to the internist. Dr. Adair has called your attention to the differential diagnosis, some points of which might be stressed.

Eclamptic hypertension is a clinical entity, characterized in the early stages by a more or less variable syndrome

but later very often by a high blood pressure, albumen and casts in the urine and a tendency to edema. Usually there is little or no blood in the urine. The kidney in this case resembles very closely the kidney as seen in cer-

Fig. XIII, Case XII. Photomicrograph showing the characteristic changes in an arterio-sclerotic kidney.

tain degenerations, such as those which follow intoxications, following fevers, mineral poisons, and so on, a condition which we very frequently call a nephrosis to differentiate it from inflammatory changes in the kidney,—inflammatory nephritis. Following labor and the puerperal period or removal of the intoxication, recovery of the kidneys is apparently complete. Possibly a few of these kidneys show some permanent damage, a supposition which is hard to prove.

We may have eclamptic hypertension associated with physical injury, especially glomerular injury. In such cases we are likely to have the eclamptic symptoms increased. Usually there are also some additional symptoms, namely, nitrogen retention, and a tendency to fixation of the specific gravity of the urine. These cases are likely to have a severe albuminuric retinitis and often show a considerable quantity of blood in the urine. After labor the eclamptic symptoms may disappear. However, we always have a residue which is aggravated over what it was before pregnancy or the most we can expect is a return of the kidneys to the condition which was present before pregnancy developed. Acute nephritis developing in pregnancy probably does not clear up entirely; there is nearly always some residue, or scarring, which, however, may not be evident clinically.

My third point is that hypertension (so-called essential hypertension) may be associated with eclampsia. Essential hypertension per se, of course, is not a cause of edema and makes a differential point. However, when the two are associated together the differential diagnosis is more difficult. The symptoms of eclampsia are likely to be increased if renal arterio-sclerosis is present. Such cases have a high blood pressure before and following eclampsia. On the other hand, as Dr. Adair has shown, hypertension cases may go clear through pregnancy without any evidences of eclampsia.

Eclamptic hypertension, glomerulonephritis and essential hypertension may therefore occur in pregnancy and one may occur in association with another. The prognosis depends upon how thoroughly the cases are analyzed and also to a certain extent upon the treatment instituted. We should therefore be very careful not to draw conclusions from insufficient data, that is, just hypertension and albumen.

DR. A. G. SCHULZE: I had the pleasure of reading Doctor Adair's paper yesterday and I made some notes on that part of the paper which he did not read this morning. If I were obliged to follow a woman through pregnancy and resort to blood pressure findings on the one hand or be obliged to resort to urinalysis on the other hand, I think I should take the blood pressure method. It has been found that in those women who show a "trace" of albumen, forty-five per cent develop toxemic symptoms, and in another series of pregnant women who developed what you would call a "large trace" of albumen only fifteen per cent developed toxemic symptoms. Therefore the amount of albumen in the urine seems to be very unreliable as an indication of eclampsia; the blood pressure reading being much better.

What is a normal blood pressure in pregnancy? I am asked that question repeatedly and I tell the patient that there is no such thing as a normal blood pressure, except in so far as you apply it to the patient at the time you take it and under the conditions and circumstances in which you take it. Three years ago, in preparing a paper for the Ramsey County Society on this question of blood pressure during pregnancy I analyzed 210 blood pressure readings taken in 50 women who were pregnant from the fourth to the ninth month, and I found that the average of these readings was 117 millimeters of mercury, which is a little below the generally accepted 120, and that they ranged from 109.5 at four months to exactly 119.5 at nine months, an elevation of ten millimeters of mercury during pregnancy. At no time, from one month to the next, was there a greater increase than three millimeters of mercury over the preceding month.

I also had 75 blood pressure readings taken at the end of pregnancy and before the patient went into labor and the average of those was 123. I had a series of 86 blood pressure readings that were taken, as near as we could determine, in the second stage of labor, and they averaged 133. I had 104 readings that were taken three hours after delivery and found that it had gone back to 120. If a pregnant woman comes to you for the first time and she has a pressure reading of 130 or 135, what does it mean? It does not mean anything in itself because her blood pressure reading before she became pregnant or before you saw her, may have been 150 and now it has come down to 130. It may be that she has been carrying a blood pressure of 130 all her life; or it may have been that earlier in pregnancy her blood pressure reading was 100, 105 or 120. It makes all the difference in the world which way the blood pressure is going, whether it is going up or going down or holding its own.

A few years ago Irving of Boston showed that if the blood pressure remains between 130 and 140 about 3 per

cent of the women would develop toxemic symptoms; if the blood pressure went between 140 and 150, 9 per cent of them developed it; if it went between 150 and 160, 25 per cent developed it; if it went between 160 and 170, 50 per cent of them developed it, and when it reached 180, 100 per cent of them developed it.

The value of blood pressure readings is not in a single individual reading but rather in a series of readings. I take blood pressure readings every time I see my patient as faithfully and systematically as I do urinalysis, and the danger in pregnancy is when it begins to go up. It has been said that if the blood pressure reaches 150 you are getting beyond a normal pregnancy.

The essayist in his paper made some remarks about a postpartum eclampsia being less severe. I used to think so, and yet some of the most severe cases of eclampsia with convulsions have all been postpartum, and I am beginning to doubt whether a postpartum eclampsia is necessarily a simple form. The essayist also said something about a double toxemia developing. I am glad that he mentioned it.

He mentioned a case of fetal death without convulsions. I would like to ask if that fact established the diagnosis of chronic nephritis. Another question I would like to ask is, are convulsions characteristic and diagnostic of eclampsia as opposed to a chronic nephritic condition. The internist brought that point out some time ago and I have been trying to observe it from the point of view of the obstetrician. Another question is the differential diagnosis between eclampsia and chronic nephritis.

DR. ARCHIBALD McDONALD: I have enjoyed reading Dr. Adair's paper, which brings out forcibly the value of the simple procedure of diagnosis. The classification of the convulsive toxemias of pregnancy is not simple, neither is it absolutely definite. We must admit two, if not three, types. First, the exacerbation of a pre-existing chronic nephritis; second, the onset of an acute condition occurring either as an infectious condition, or as the so-called kidney of pregnancy. For both of these types elevation of blood pressure, together with other signs of nephritis, will give ample warning at a time when proper treatment will usually prevent an onset of uremic convulsions.

There is a third type, which I think of as eclampsia. Its etiology is not known, but its occurrence as an entity must be admitted. It may occur in women who have no edema, no albuminuria, and often no marked elevation of blood pressure. The condition frequently clears up with no evidence of permanent kidney lesion and, unlike the nephritic toxemias, does not tend to recur in subsequent pregnancies. It seems to depend upon some temporary disturbance, associated with that particular pregnancy. Possibly a recent attempt to prove an anaphylactic reaction of the mother to the fetal blood, which is assumed to be absorbed through abnormal placenta, may throw important light upon the etiology.

I believe that the premonitory signs, commonly described as pre-eclamptic, are really of more help and value in conditions with the uremic type of convulsion, that true eclamptic convulsions may occur equally often in the

nephritic. In fact, the nephritic changes may and do predispose to true eclamptic convulsions, but there is a distinct type of eclampsia for which we must hope that future work will develop characteristic preconvulsive evidence.

DR. F. J. HIRSCHBOECK: There has always been a great deal of confusion among clinicians regarding the terminology relative to convulsions in nephritis and so called "eclamptic" convulsions. One of the speakers has referred to the three types of hypertension associated with pregnancy: the eclamptic hypertension, essential hypertension and renal hypertension. The differentiation is not as difficult as it may seem. Essential hypertension is relatively rare in women in the child-bearing period, and usually does not develop until the menopause, so that in a pregnant woman with hypertension a diagnosis of primary cardiovascular disease must be made with caution.

I believe the term "eclampsia" is not used as often as it should be used, and in fact it is possible that the convulsions occurring even in renal insufficiency and uremia are eclamptic manifestations and not an evidence of non-protein nitrogen retention.

The true eclamptic has a rather characteristic appearance: his face is florid during the convulsion, usually cyanotic, and in appearance appears to be relatively well before the attack. Chemical studies before the convulsion usually show no increase, or only a very slight increase, in the end products of protein digestion in the blood, and the blood picture, from the standpoint of its individual cellular constituents and hemoglobin, is normal. On the contrary, a patient who is uremic, and who has symptoms of renal insufficiency, is pale, anemic, and looks ill. The blood count is materially reduced, and the blood chemical studies show an increase in the end products of protein digestion. The true uremic does not have convulsions very often, even in the terminal stage, which is characterized more by a twitching of the extremities and muscles, with a gradual deepening coma, and rarely convulsions. The prognosis in eclamptic convulsions is good, if there is no disturbance to a marked degree in the renal function, and is benefited by spinal puncture or venesection, which would have no influence, or which might result in a deleterious effect, in a true nephritis.

DR. J. C. LITZENBERG: In two or three of Doctor Adair's cases he illustrated the significance of blood pressure after the delivery. Something of a drop is the usual occurrence and then a rise to either the height it was before or approaching it. Then a gradual drop or a rapid drop after delivery, and it is of that I wish to speak as indicating something of prognosis. There seems to be some evidence that we can get an inkling of what the ultimate prognosis of the case may be by the rapidity with which the blood pressure drops after delivery.

It is the usual thing in a case with a good prognosis for the blood pressure to drop fairly rapidly in a comparatively short time to a normal reading. There are on the other hand cases in which the blood pressure drops very slowly. It may be considerable of an assumption to say that these are cases in which the kidney injury has been greater than those in which the drop has been more rapid, but I

believe it to be true. It is a blood pressure condition of this kind in which there is always a residue in the kidney referred to by Dr. Gardner. I take it that he meant residue of injury.

As Doctor Bell of the Department of Pathology at the University has emphasized many times, the human kidney has much more tissue than is necessary to sustain life. Therefore, even if the kidney be injured there may be enough normal kidney tissue left for the woman to go on with normal findings. Yet those women, if they become pregnant again, sometimes repeat this hypertension story. Kidney injury in toxemia of pregnancy is a mighty interesting subject to me, I wish we could know more about it. I am convinced through my experience in the last few years that there are some of those kidneys that are permanently injured.

I had one case of eclampsia that I had the privilege of following for twelve years. She had eclampsia in her first pregnancy. Her blood pressure returned to normal very, very slowly; it took many weeks. She also had a moderate albuminuria for those many weeks. She finally returned to normal, remained so for nearly twelve years, that is, normal urinary findings. She became pregnant twelve years after the first pregnancy. She went through the second pregnancy apparently normal for seven months, then she had a beginning hypertension but no albumen until she had had the moderate hypertension for several weeks. Then all of a sudden, in the ninth month of pregnancy, she had a rapid rise of blood pressure which made it necessary to induce labor.

My guess in this case was that her kidneys were badly injured and there was enough normal kidney tissue left for apparently normal function. She was in good health, there was no abnormal urinary findings and even with the subsequently pregnancy the kidney was able to function normally until the burden began to be too heavy, then there was not enough tissue to carry on. This is only an assumption, but I think it indicates the prognosis.

I want to speak about the fallacy of average blood pres-

sure readings. A few years ago I made an analysis of the blood pressure readings of 526 cases and I came to the same conclusion that Dr. Schulze came to, namely, that there was a normal rise in blood pressure during pregnancy, that was by averaging my readings. It occurred to me that perhaps I had better analyze what occurred in the individual cases. So I took the average blood pressure readings of each case and I averaged them and I found that there was no rise of blood pressure during the normal pregnancy, although that had always been my impression and my figures seemed to prove it. Of course, I dealt with only 526 cases. That is not very many. There seemed not to be a rise in blood pressure, although I admit it is hard for me to get away from the impression that there is.

DR. F. L. ADAIR (closing): In answer to the questions regarding the fatal case, I would say that the patient was made worse with each succeeding pregnancy, and further injury was added to the lesion she had before. The cause of death in this case was the result of uremia which resulted from the arterio-sclerotic kidney.

Are convulsions peculiar to eclampsias? I don't think they are, but Dr. Hirschboeck has covered the differential diagnosis between uremia and eclampsia and I will not go further into that question. Of course, we have other findings than hypertension which establish a diagnosis of eclampsia. We occasionally run across an epileptic, and it is not unusual to have a case of hystero-epilepsy. I think we should usually be able to differentiate between uremia and eclampsia by the patient's urinary findings and blood chemistry, if you wish to go into it. I think a fairly good way to differentiate a uremic case from an eclamptic condition is one I think every one could apply. First, a careful history; second, physical examination for evidence of chronic renal disease; third, urinary examination—albumin with casts and cytologic elements in the nephritic, and little except albuminuria in eclampsias; fourth, the rapidly developing clinical course of eclampsia. These things should lead one to a correct diagnosis in most cases where more elaborate diagnostic measures are not available.

TOO MANY COUNTY SOCIETIES SLEEPING

Too many of our county societies are sleeping, arousing just enough at necessary intervals to keep their names on the books. The council is held responsible for them under the constitution and by-laws of the state association. It is hard to believe that the councils in some instances realize their responsibility. Perfunctory reports made at some annual meetings indicate that they do not. Councilors' reports made up from letters sent out the week before the annual meeting of the state association are not reports—they are evasions. Councilors are supposed to visit—actually visit—the societies in their respective districts at least once each year. How many do so? Councilors are supposed to "inquire into the condition of the profession," to "organize component societies where none exist," to be "peace makers and censors," to "improve the zeal" of county societies. These things cannot be done by writing a few letters ten days before the annual meeting and then turning in what

purports to be a report, which, formulated in that manner, nearly always makes it appear that everybody is happy and that medical organization is 100 per cent efficient, when, as a matter of fact, the formality of a funeral is about all that is necessary, in some instances, to carry out the very distinct indications as presented by the situation that really exists.

Within thirty days, the organization of five independent local medical societies has been reported in territory already occupied by county medical societies supposed to be alive and going. What's the matter? Why are the societies already in existence not meeting the needs of their members? Why do they find it necessary or desirable to go off and form new and independent societies? Those things are for the councilors in the respective districts to find out. And it is their duty to try to remedy any condition in the county societies concerned that is responsible for these undesirable situations.—*A. M. A. Bulletin*, Dec., 1923.

METASTASIS IN BREAST CANCER*

W. A. COVENTRY, M.D., F.A.C.S.

The Duluth Clinic

Duluth

The object in bringing this subject before you today is to review with you several outstanding features that have been revealed by the study of some thirty-six cases of breast cancer that have been operated by us and in which the "follow up" has been completed.

The question of metastases in their relation to the prognosis, has been an interesting study.

The chief avenues of metastases in breast cancer are: (1) axillary glands; (2) to the clavicular chain of glands; (3) through the chest wall to the mediastinum; (4) to the peritoneal cavity; (5) local recurrences in the skin; (6) bony or skeletal metastasis.

The question must also be considered from the proper preoperative, operative and postoperative standpoints.

Axillary Involvement.—Our series show that 89 per cent had axillary involvement previous to operation. This percentage is about the same as that reported in other series of cases in the literature.

The presence of axillary involvement has not deterred us from advising operation, but especially indicates the desirability of preoperative roentgen therapy in this area. The operation has always included the removal of the glands and the gland bearing tissue about the vessels in the axilla.

Postoperatively 80 per cent of these cases have had intensive roentgen therapy, and in the cases operated 70 per cent have shown no evidence of recurrence of the axilla involvement. The other 30 per cent, however, did recur in the axilla. This very small number of recurrences in our opinion speaks very well for the effect of roentgen-ray therapy to the more superficial gland bearing areas.

Cases With Metastasis Into the Clavicular Group of Glands, Either Subclavicular or Supraclavicular.—This type has not been as numerous as the axillary type, primary metastases being noted in only 11 per cent of the cases. Recurrence in these cases has taken place in only 0.5 per cent.

It is our practice to first treat these cases with intensive roentgen-ray therapy before operation,

and then at the time of operation to remove all the glands and gland bearing areas up to and under the clavicle.

However, it does seem that the glands are better controlled by roentgen-ray therapy in the supraclavicular group than in the axillary group. This may be due to the fact that they are more superficial than the axillary group of glands.

Radium, in the treatment of this supraclavicular type of glands, has not been tried.

Fig. 1. Case 27120. Operated Oct. 22, 1921. July 18, 1922, shows Ca. Metastasis sixth dorsal vertebra.

Metastasis Through the Chest Wall to the Mediastinum.—Metastasis through the chest wall, to the mediastinum, in to the pleura, involving the lung, and extending to the opposite breast, has occurred in a number of cases. There were six cases that died from lung involvement. However, three of these cases died from a general carcinomatosis, and in these cases one must consider as to whether the metastasis was primarily through the chest wall or whether it was due to malignant emboli or metastasis from some other source. There have been no cases of malignant involvement of the pleura.

Metastasis to the opposite breast has occurred in

*Presented at the annual meeting of the Minnesota State Medical Association, St. Paul, October, 1923.

0.8 per cent of the cases, the metastasis always occurring late.

One must also consider whether in these cases we have to deal with a new malignancy occurring in the opposite breast or to metastasis from the primary growth.

This type of metastasis also offers very satisfactory results with roentgen-ray therapy.

Recurrences to the Abdominal Cavity.—Recurrences to the abdominal cavity through the lymphatics has not been observed in our series, and a review of all the available literature reveals the fact that such avenues are possible, but it is more likely that liver metastasis is secondary to metastasis from bone or lung carcinoma.

Local Recurrences in the Skin Over the Amputated Area.—These have only occurred in 2.8 per cent of cases. This, we think, is a very good record, and believe it is due to three reasons: (1) Preoperative roentgen-ray therapy; (2) a wide dissection of the breast; (3) systematic postoperative roentgen-ray therapy.

Skeletal Metastasis.—Metastasis into the bone offers a very interesting study. Our series showed 0.25 per cent of those operated developed a bone metastasis.

Whether or not those cases had some metastasis before operation we do not know because this was

Fig. 2. Case 33611. Operated May 19, 1923. Picture Oct. 1, 1923, shows metastases left head of femur and beginning ilium.

not investigated before operation in any of the cases.

Metastasis occurs in the order of frequency in the head of the femur, the ilium, spine, sternum, ribs, skull and lower jaw.

Fig. 3. Case 26918. Operated Sept. 27, 1921. Picture Aug. 1, 1922, shows extensive metastasis of spine with marked deformity.

The elbow and the knee joint, and all of that part of the skeleton below the head of the femur, seem to escape metastasis.

Skeletal metastasis seems to become very well established before any symptoms arise, the only symptom being that of pain, which is very severe. The unfortunate point here is that although roentgen-ray therapy will to a certain extent relieve the pain, it seems to have, in our experience, no decided beneficial effect upon the process once it has become established.

The roentgen plates in these cases deserve very careful study, and are best compared with the normal in order to bring out the rarefaction of the bone.

Metastasis undoubtedly occurs by way of the lymph channels, although some authors suggest that it may come through the blood stream.

Kauffman, in his article on metastasis, finds that 52 per cent of those dead from carcinoma have skeletal metastasis.

It is my belief that this type of metastasis is more frequent than is generally supposed, and that

roentgen pictures of the head of the femur, the ilium and the spine should be taken in all cases of carcinoma of the breast before operation. It has been repeatedly demonstrated that local and glandular infection can be controlled and cured by the use of the roentgen ray. It has also been shown that once the metastasis reaches the bones the roentgen ray has practically no effect, except a palliative one.

It is universally agreed that the degree of malignancy in carcinoma is due to the type of cell found in the tumor. Tumor masses showing hyalinization and fibrosis generally speak for longevity, while those cells of a more embryonic type speak for a short life. The unknown quantity of the degree of resistance of the patient also must be taken into consideration. These facts have been very well shown by McCarty and Sistrunk in their very admirable work. It is generally recognized that the size of the tumor in the breast is of no particular prognostic value, but the involvement of palpable glands, with fixation, decreases the chances more than one-half for a favorable outcome.

Fig. 4. Case 12660. Operated Sept. 1, 1922. Picture Apr. 10, 1923, shows beginning carcinomatous involvement vertebrae. Now has metastasis to ilium and femur.

It is also recognized that cancer, appearing after fifty years of age, is more favorable as to prognosis than that occurring before fifty, and that the younger the individual the more increased is the cell activity, and the more rapid the demise.

It is our opinion, gathered from these statistics, that it is much better to give the patient the benefit of the doubt and remove all fibromas, cystic mastitis and so-called "lumps" in the breast, this being a much safer procedure than to allow them to remain until such time as carcinoma develops

and metastasis has taken place, when the hopes of an ultimate recovery are certainly not good.

We believe, in view of the fact that skeletal metastasis is so common, and that when once found

Fig. 5. Case 29128. Operated Nov. 28, 1922. Picture Aug. 22, 1923, shows extensive metastasis ca. in femur.

the prognosis is hopeless, that it is better practice in all cases of breast carcinoma to take roentgen pictures of the ilium, head of the femur and the spine, so as to determine before operation whether there is any metastasis in these bones. If metastasis is found it would be very much better to refuse operation and attempt to treat with the roentgen ray, feeling sure that the ultimate outcome will be as favorable, and life will probably be increased by such a procedure.

We are also of the opinion that roentgen-ray therapy, from seven to ten days before operation, and then intensive system roentgen-ray therapy, giving about 130 per cent of the maximum skin dose over the local area, the glands, and also skeletal bones involved, is, in the line of our present knowledge, the best procedure we have for the treatment of carcinoma of the breast.

Lee reports that the length of life after recurrence was six and one-half months without irradiation, but after postoperative irradiation it jumped to two years and four months.

Radium has not been used because we believed that better penetration could be obtained with roentgen ray.

Conclusions.—1. Metastasis into the skin, axillary glands, supraclavicular region, and in the chest wall, is unfavorable, but the condition can be controlled or arrested by the intelligent use of roentgen-ray therapy.

2. Carcinoma of the opposite breast does not necessarily mean a metastatic involvement.

3. Metastasis into the skeletal structures, more particularly the ilium, the head of the femur and the spine, offers an exceedingly painful course and unfavorable prognosis. The pain, however, may be controlled to some extent by the roentgen ray.

4. We think it better practice to take roentgen ray pictures of the femur, the ilium, and the spine, before operative measures are instituted, and if rarefaction is found it would be much better to refuse operation in these cases.

DISCUSSION

DR. W. E. SISTRUNK, Rochester: I was very much interested in listening to Dr. Coventry's paper, and I think he has brought out some very interesting and important facts. It has been customary with us for a good many years to take x-ray pictures of the lung and chest preliminary to operations for cancer of the breast, but up to the present time we have never made a routine habit of taking x-ray pictures of the bones. We have felt that the first symptoms of bone metastasis which would be recognized as being symptoms were symptoms of pain. It seemed as though

we very rarely were able to find involvement in bones without having some history of preliminary pain. In fact, I am able to recall one or two patients in whom we suspected possible bone metastasis, in whom the x-ray plates were

Fig. 7. Case 6046. Operated June 9, 1921. Picture Aug. 5, 1922, shows metastasis to ilium.

negative and who later continued to have symptoms and finally showed positive plates. But I think that the doctor's suggestion that the bones which seem most commonly involved be given roentgen-ray examinations—and especially in cases where glandular involvement is present—is certainly a very good one, and we all ought to bear it in mind.

I recently had an opportunity to review the histories of ninety-seven patients in whom we felt that we had fairly accurate data in regard to the points at which recurrences had occurred following radical operations of cancer of the breast. In this group a number died from general metastasis, but when we took them as a whole and studied them we found that in forty-seven per cent of the cases there were evidences of recurrence in the skin. Twenty-eight per cent of these had had glandular involvement at the time of the operation, and ten and a half per cent had had no glandular involvement at the time of the operation. Then we found another very interesting point and that was that in sixty and a half per cent of these people who came back with local recurrences we were able to demonstrate recurrences in other portions of the body at the same time.

I think that Dr. Coventry is correct in thinking that metastasis in cancer of the breast occurs very much more frequently in patients who have glandular involvement at the time of the operation. Now the time at which metastasis occurs in glands varies considerably, I think, in different patients. It is not a very uncommon thing to see a patient who has the type of carcinoma which probably has been present for several years or longer without any metastasis that we are able to locate. In these patients the growth is probably surrounded by a tremendous amount of fibroid tissue, and they are able to hold it in check. But in the ordinary patient at some time during the course of the disease metastasis will usually occur. It probably comes, I think, from the breaking down of the carcinoma

which allows a certain fluid to collect in the tumor which is picked up by the lymphatics. I imagine that all lymphatics which drain that region are likely to be affected at that time, and that that accounts for the frequent recurrences following operations for cancer of the breast. It is really appalling to see how advanced the majority of patients are in the disease when they consult you in regard to the trouble.

Recently in a study of two hundred and eighteen patients whom we were able to follow after operations for cancer of the breast, we found that the glands were involved in sixty and a half per cent of the people at the time of operation, and that in this group twenty of these people had ulcerated growths at the time of operation and sixteen had diffused growths which were scattered throughout the entire breast. Now the operations which we do give results which are almost entirely dependent upon the stage of the disease at which we operate. I think it is interesting to note the difference which comes following operative procedures in different stages of the disease. For instance, in going over this series which I have just mentioned, I ran across a small group of six patients who were operated upon for cancer of the breast in which a simple amputation was done. The condition was not recognized at the time of operation but later was found by the pathologist to be a definite cancer but an early type of cancer. But nothing further was ever done. We traced five of these six: Four were alive—66.66 per cent—for five to eight years after operation; one had died four years afterwards but we could not ascertain the cause of death; and another was traced for two years and then we lost track of her. But they were simple amputations and 66.66 per cent were alive with the possibility of another being alive.

Now when we studied the people who had been operated upon when the glands were not involved we found that in eighty-six patients, 64 per cent were alive from five to eight years after operation; but we know that in three of these who were alive recurrences had either been present or were present at the time. We took another group and considered people who had involvement of the glands. We found that of 132 people with involvement of the glands only 19 per cent were alive; and that with twenty people with ulcerated growths 85 per cent were dead in five years; and that with sixteen diffuse growths all were dead within five years.

So I think we ought to bear in mind the importance of operating on these cases early. It behooves us to try to educate the public to have all breast tumors examined early.

DR. C. A. DONALDSON, Minneapolis: It seems to me the important point in the doctor's paper is the question of radiating the bone for diagnosis prior to operation. I was surprised a short time ago, without the presence of pain, to find both femurs very seriously involved in breast carcinoma. There was no pain further than perhaps the first or second lumbar vertebra. This constitutes a very important preparation.

For a long time we have treated with the 125-kilovolt type of machine. We know now that it is impossible to penetrate with a cancer-killing dose more than about three

or four centimeters with such voltage. So if we are going to penetrate deeper we must use stronger apparatus.

On the question of operative work and the metastasis that occurs following it, there is a very interesting discussion by Handley in his second edition, comparing the work of Halstead and Cheyne. He describes Halstead's work as giving a wider dissection of the skin, and Cheyne's work as giving a wider dissection of the deep fascia; and he gives the results in their skin recurrences: Halstead getting sixteen per cent, I believe, and Cheyne six per cent skin recurrences. Doctor Coventry spoke of the wide dissection but he did not say whether it was of skin and fascia both or whether it was the dissection of fascia alone.

There are two important considerations that should modify our treatment a good deal. We do know that sufficient radiation kills cancer cells. The difficulty has been to get sufficient radiation to the widespread metastases, and more important is the fact that radiated tissue, when transplanted, does not grow. There is no use sending a neglected case to the roentgenologist when nothing can be done by the surgeon. We might as well recognize that fact. You can do something to modify the course of the disease, and you can give relief from pain; but you might as well send these folks home if they expect to be cured. Now I think those are the important factors.

DR. JAMES A. JOHNSON, Minneapolis: I am very pleased to have heard this splendid paper. Dr. Coventry has very carefully outlined the points of metastasis that occur in breast carcinoma.

There is one point of metastasis that I would like to emphasize and that is to the neck of the femur. Not infrequently a metastatic process in this location is overlooked. I can recall, while in one of the large Chicago Clinics, that I had on my service at one time three cases of pathologic fracture of the neck of the femur, unrecognized as such, due to metastasis from a breast carcinoma. One had been operated for carcinoma of the breast in the same hospital five years previous, with no local return and no evidence of foci in any other place. The other two were in younger individuals and had been treated for an ununited fracture for some time. The primary lesion in the breast had not been recognized—all three had received their fractures from a trivial injury which should have put the clinician on his guard at once.

I agree with Dr. Coventry that preliminary to operation it is essential to x-ray the lung and also the long bones, especially if there is any local bone pain or discomfort. This is especially important in advanced cases.

I also believe a preliminary x-ray treatment is of some value. I think, however, it is a mistake to carry it over a period of months when often much valuable time is lost. The operation should be undertaken shortly after the initial radiation. I believe post-operative radiation is of considerable value and should be continued for several months.

DR. W. A. COVENTRY, Duluth (closing): Only one word: The thing which stimulated me to this study was the fact that three of these cases developed bone metastasis within six months after they were operated. The patients were just getting on their feet and feeling quite happy, and all at once they were condemned to a slow death.

THE DIAGNOSIS OF ACUTE APPENDICITIS IN CHILDREN*

HENRY F. HELMHOLZ, M.D.

Section on Pediatrics

Mayo Clinic, Rochester, Minnesota

My reason for bringing this subject before you today is twofold: first, because there are still too many unnecessary deaths among children with appendicitis, because of failure to make early diagnosis, and second, because it is a subject in which the general practitioner and surgeon are as much interested as the pediatrician.

In our series of fifteen cases under five, only four patients were brought to the surgeon inside of forty-eight hours after onset, and nine had generalized peritonitis (Table 1). It is agreed that if appendicitis can be diagnosed in the first twenty-four hours and the patient promptly operated on, the mortality is practically nil. Furthermore, in no condition is the cure so radical and complete as in cases of appendicitis after the removal of an infected appendix. It is evident, therefore, that all of our efforts should be directed toward early recognition of the condition, which may be accomplished quite successfully in the adult, as is seen by the mortality statistics of most hospitals. In infancy and childhood, the diagnosis is very much more difficult. The insidiousness of onset and the rapidity with which rupture of the appendix occurs make it difficult to get the patient to the surgeon before the infection has spread beyond the confines of the appendix. As Finney has emphasized, in the adult the tendency is to mistake other conditions for appendicitis, whereas in the child the tendency is to mistake appendicitis for some minor condition. Pneumonia is the one great exception to this rule, for not infrequently central pneumonia of the right lower lobe may give symptoms suggestive of appendicitis.

The younger the child, the more difficult the diagnosis of appendicitis, but fortunately also the less likely is the condition to be appendicitis. In a series of 16,571 cases of appendicitis collected by Kelly, only 2 per cent of the patients were under six years. Eight per cent were between six and ten years, and 16 per cent between ten and fifteen. Although the disease is very infrequent in the first

two years of life, the extreme mortality of 50 per cent in Abt's series of eighty cases makes an early recognition of the condition imperative. In most of his cases the diagnosis was not made until the inflammatory process had extended beyond the appendix, and in a number it was made only at necropsy. Our series of fifteen cases in patients under five years emphasizes the same points, the late diagnosis and early peritoneal involvement.

As brought out by these data, no greater responsibility presents itself to the physician than the decision in the case of an obscure abdominal condition. Although appendicitis is easy to diagnose early when it appears in its textbook form, in its atypical manifestation it is likely to tax to the utmost the diagnostic acumen of the physician.

*Five interval operations.

HISTORY

The younger the child, the less probable, naturally, is the history of previous attacks. Churchman describes the case of an infant with an appendiceal abscess at twenty-seven months, who had had two definite previous attacks. The nature of the attacks is sometimes typical, sometimes, in retrospect only, suspicious of previous appendicitis.

In the group of fifty-three patients, seen during 1921 and 1922, in the Mayo Clinic, about 30 per cent had a history of previous attacks, and in the group of fifteen patients up to five years, only 6 per cent had such a history. In most instances it is a rather indefinite attack of abdominal pain associated with vomiting and slight indigestion. This rapidly passes off. As an exception to this rule, diarrhea of twelve hours' duration, without pain or vomiting and, so far as could be ascer-

*Read before the meeting of the Minnesota State Medical Association, St. Paul, October 10-12, 1923.

tained, no indiscretion in diet, was the only subjective evidence of two attacks. In the second attack local tenderness over McBurney's point directed attention to the real source of the trouble. At operation a long appendix, firmly adherent in its entire length to the posterior wall of the cecum, was found.

The history is further of importance in eliminating the abdominal prodromes of certain infectious diseases. The onset of measles, typhoid, or rheumatic fever may simulate appendicitis. Finney cites a case in which the day after the removal of a swollen, thickened appendix the child developed measles. In a second case, similar pain in the right iliac fossa cleared up when the measles broke out the following day, and in a third case, in which the patient was not operated on because the symptoms were indefinite and the brother had measles, operation was delayed until after the appendix had ruptured.

The increased frequency of appendicitis after gripe infections, and following an attack of typhoid, or ulceration of the bowel, makes these diseases of importance as possible etiologic factors.

In some cases there was a definite history of a previous appendiceal attack. This raises the question of whether one attack is sufficient indication for removal of the appendix in the interval.

SYMPTOMS AND SIGNS

The symptoms that are almost always present are vomiting and pain, but these symptoms are so frequently encountered in childhood at the onset of illnesses such as the acute exanthemas, respiratory infections, indiscretions in diet, and gastroenteritis, that we are prone to consider them lightly. If vomiting persists after the stomach has been emptied, and if pain continues also, it is of great significance. Pain at first is general, referred to the epigastrium, or around the umbilicus. Only later is it referred to the right lower quadrant. According to Bruening, the first pain is caused by excessive contraction in the appendix and cecum, and is referable to the ganglia. The local pain is due to irritation of the peritoneum. Not infrequently the attack may begin with sharp, acute pain in the right lower quadrant, colic-like in character and disappearing for a considerable interval, only to reappear with greater intensity.

In the fifty-three cases there were only two associated with diarrhea and retrocecal position of the appendix, in which the pain was entirely absent,

although there was tenderness on deep pressure. In seven of the fifty-three cases there was no vomiting, and in two others nausea, but no vomiting was noted. In only one case was there neither vomiting nor pain. The character of the pain varies tremendously, from a slight pain that permits a child to go about its play or walk to school, to an acute pain that doubles a boy up suddenly while he is working in the field. Constipation is usually not present, and diarrhea was present in five of my series of cases.

Pain on urination should always suggest the possibility of an irritation due to an inflamed appendix. It occurred in 8 per cent of Porter's cases. It appears too infrequently to be of any great help, and is of importance only in that pyelitis may cause a similar clinical picture, associated, however, with typical urinary findings.

Flexion of the right thigh, coming on acutely, or bending of the trunk toward the affected side is suggestive of appendicitis.

Respiratory symptoms, cough, expiratory grunt, and hyperpnea, are of value in suggesting a possible respiratory cause for pain localized over McBurney's point. The abdominal pain associated with infections of the throat may at times be suggestive of appendicitis.

Tenderness is perhaps the most important sign that can be elicited in the diagnosis of acute appendicitis. When found locally, it is of far greater significance than any other single factor in the diagnosis. It was present in all of the cases examined. It may be absent, however, particularly in young children, when the process has involved the peritoneum and an exudate fills the peritoneal cavity. It may be present for only a short time. One patient whose complete attack lasted only three hours, was seen by a surgeon after that interval, and he could find nothing. Another similar attack followed; with both there were fever, vomiting, pain, and a leukocytosis. An interval operation showed an appendix folded to a right angle and greatly thickened distal to the angle. Occasionally the tenderness may be on the left side, as in cases reported by Schellong and Porter, when the appendix extends into the left lower quadrant behind the bladder.

Rigidity of the muscles of the abdomen is usually found, but may be absent. The greatest difficulty in determination of both tenderness and rigidity is that the little patient, whether through fear,

crying, or bad temper, holds his abdominal muscles so rigid that palpation is useless. A few moments used in first winning the patient's confidence is frequently the basis of a successful examination. The confidence of the patient is particularly essential for a successful rectal examination. Rarely is it of use under four or five years of age as a means of determining tenderness, but it is helpful in determining infiltration or the presence of a mass. When children over five will co-operate, tenderness on the right side as compared with the left, is one of the most helpful signs in the diagnosis of appendicitis, particularly in the differential diagnosis from pneumonia.

If ether is used for the examination, the patient should be prepared so that he can be operated on immediately, if necessary.

clear cells is very suggestive of appendicitis, especially if the eosinophils are absent.

Local tenderness which later becomes general usually means perforation and generalized peritonitis. A mass in the right lower quadrant in an acute condition is usually an appendiceal abscess, although it may be merely the omentum folded around an inflamed appendix. A mesenteric cyst in the right lower quadrant may give symptoms and signs indistinguishable from those of appendicitis.

DIFFERENTIAL DIAGNOSIS

It is to be emphasized again that a differential diagnosis should be based on the history, the symptoms and signs, and a complete, careful examination of the entire patient. In this way only can we avoid operating for appendicitis on patients

TABLE 2
DIFFERENTIAL DIAGNOSIS

	Pneumonia	Appendicitis
History	Previous cold or cough Chest pain	Exceptionally, grippe Usually none
Abdominal pain	Severe, constant, general	Paroxysmal, less intense, local
Vomiting	14 per cent	70 per cent
Diarrhea	Common	Uncommon
Facies	Appearance of illness. Dilatation of alar nasi	Uncomplicated, not seen
Respiratory symptoms	Shallow abdominal breathing Expiratory grunt Slight dullness? Distant tubular breathing?	Shallow breathing Costal None
Abdominal tenderness	Superficial, severe Diffuse higher in abdomen No worse on deep pressure	Slight or severe More marked on deep pressure Local
Rectal examination	Negative	Tenderness on right side
Roentgen-ray examination of chest	Positive	Negative
Leukocytes	20,000 to 50,000 (uncomplicated)	10,000 to 20,000
Temperature	103° to 105°	99 to 102°

The child's temperature is usually higher than the adult's, ranging between 98.6° and 102°.

The leukocytes are usually definitely increased, the ordinary count ranging between 15,000 and 20,000. Occasionally counts between 20,000 and 30,000 are found, and exceptional counts as high as 40,000 have been noted, even with an acute unruptured appendix. The differential count, particularly a low count, is of the greatest importance. A low leukocyte count without a percentage increase in the polymorphonuclear cells usually excludes acute appendicitis. Eight thousand leukocytes with 85 to 90 per cent of polymorphonu-

who do not have it, and not overlook the condition in patients who need operation. In making a differential diagnosis we have to consider first those conditions outside of the abdominal cavity, namely, infections of the respiratory tract, prodromes of acute infectious diseases, measles, scarlet fever, typhoid fever with local pain and a polymorphonuclear leukocytosis, and osteomyelitis of the femur or ilium. In differentiating it from pneumonia, the following points, as emphasized by Adams and Berger, are to be considered (Table 2).

In the same way patients with pericarditis (Breneman) have been operated on for appendicitis,

due to referred pain, probably caused by irritation of the diaphragmatic pleura.

In the prodromal stage of acute infectious fevers and acute tonsillitis, the sudden onset, nausea, vomiting, abdominal pain, and local tenderness make a picture that is difficult to evaluate unless one has a careful history of exposure, and in the case of measles a leukocyte count and the probable presence of Koplik's spots at that stage. In one of three cases, all of which proved to be typhoid, because of local tenderness and polymorphonuclear leukocytosis the appendix was removed.

Osteomyelitis of the ilium may present symptoms that are differentiated from those of appendicitis with difficulty. I recently observed such a case, in which, however, the operation revealed that it was an appendiceal abscess and not a subperiosteal abscess as we had at first suspected. Finney cites a case in detail in which osteomyelitis of the upper femur simulated acute appendicitis, and was not rightly diagnosed until an abscess formed. An acute psoas abscess may give similar difficulty.

In cyclic vomiting the history of previous similar attacks, absence of local tenderness, and normal leukocyte count are usually distinctive. The danger in these cases is that the parents may mistake an acute appendicitis for merely another attack of cyclic vomiting, and call the physician only after the patient has grown progressively worse as a result of a ruptured appendix.

Conditions within the abdominal cavity that are likely to come into consideration are gastro-intestinal colic, mesenteric lymphadenitis (Brenneman), cysts of the mesentery, and intussusception of Meckel's diverticulum. Inflammation of Meckel's diverticulum may give a picture of appendicitis, but more frequently the case resembles intestinal obstruction due to volvulus.

Mesenteric lymphadenitis is described by Brenneman as giving a clinical picture identical with that of appendicitis. Lee reports two cases in which operation was performed, and enlarged glands found instead of the expected appendicitis. Cysts of the mesentery may cause acute attacks of pain localizing in the right lower quadrant with tenderness and a mass. In the case seen the pain was extremely severe, but usually lasted only a short time.

Attacks of colic are common in infants, particularly when too frequently fed. In older children there is usually some indiscretion in diet which ac-

counts for the pain. The attacks are paroxysmal and usually relieved by pressure. Between attacks of pain there is no local nor general tenderness, no fever, and if a leukocytosis is present, it is generally lymphatic in character.

Intussusception is commonest when appendicitis is rarest, that is, in the first two years of life. The sudden onset with periodic attacks of pain, absence of fever, constipation, bloody mucus from bowels, tumor, and no local tenderness make a characteristic picture, that is not likely to be confounded with appendicitis except late, when the invaginated bowel might suggest an appendiceal abscess.

CONCLUSIONS

1. Every acute abdominal condition in childhood should be considered appendicitis until it has been proved otherwise.

2. Acute appendicitis in infancy and childhood owes its peculiarity to the insidiousness of onset and its tendency to rapid perforation. Early diagnosis, therefore, is essential to a reduction of the mortality.

3. The dangers of appendicitis in children should be explained to parents, so as to make surgical aid available at a time when life can be saved.

4. The indiscriminate giving of cathartics to children with abdominal symptoms is an unwarranted and often dangerous procedure. Physicians should instruct parents as to this danger.

DISCUSSION

DR. FREDERICK C. RODDA, Minneapolis: Our present conception of appendicitis is that it begins as an infection of the mucosa and probably in most cases is hematogenous in origin. Dr. Helmholtz has said it frequently follows infection that swings around to various parts of the body. However, I would call to your attention some work done by Rheindorf, during the last two years, in which he has found the ascaris in the appendix at the time of operation. He contends that the worm produces toxic substances which injure the mucosa, and is a determinative factor in the inflammation. Just how important this is, I do not know. We have given up the idea that worms cause any particular trouble,—we may have to revise our opinion.

In the differential diagnosis, Dr. Helmholtz did not stress pyelitis. I think an acute pyelonephritis, especially if it involves the right kidney, is liable to produce symptoms which simulate appendicitis. It is to be ruled out by urinalysis. The differential diagnosis of pneumonia and appendicitis is extremely difficult. If one suspects appendicitis, it is dangerous to delay for developments. The only sure means of differentiation is the fluoroscope or x-ray plate.

We have been impressed, in the last few years, with the frequency with which large mesenteric and retroperitoneal glands are found with an appendicitis. Dr. Helmholtz has mentioned this, and it has also been emphasized by Brennenman and Hudson. They are frequently found in groups, some of them as large as beans. We have obtained negative tuberculin reactions in these cases. They are evidently not tuberculous. Sections of some of these glands show a simple hyperplasia. Whether they are secondary to the appendicitis or arise from some independent source, we do not know. Brennenman, however, thinks at times they are the source of pain, and must be differentiated from acute appendicitis.

I should like to remark about the interpretation of the white blood count in cases of appendicitis. It is a fact that the white blood count in children is not as reliable as in the adult. At times the white blood count will be of very little help. I have in mind a little patient who had a white count of 10,000. The surgeon was inclined to think because of the low count that there was no pus present. At the time of the operation, however, a pocket of pus was found. He was then of the opinion that recovery was questionable because of the low count, and interpreting it as low resistance. However, the child made a speedy, uncomplicated recovery. I would feel that the history, physical findings and the exclusion of other conditions are the most valuable. I would put the white blood count at the bottom of the list of helpful findings in the diagnosis of appendicitis.

DR. E. S. JUDD, Rochester: Dr. Helmholtz asked me to discuss this paper for one or two reasons: he knows that I have had a good deal of difficulty in diagnosing appendicitis in children; possibly the other is that I have operated upon some of the cases that he has presented. I do not know of any problem that is more difficult than the diagnosis of acute appendicitis in children, at the first attack. There are so many other conditions that must be

considered. As I think over the cases I have seen, I recall pneumonia as a frequent complication, or a condition which must be ruled out if possible before a diagnosis is definitely made. We have had cases under observation for several hours endeavoring to make a differential diagnosis between an acute appendicitis and beginning pneumonia. I have afterward operated on these same cases. In some instances where we decided that the condition must be due to acute appendicitis, we found very little wrong with the appendix, but the child afterward developed a frank pneumonia. Undoubtedly they had a pneumonia from the start. On the other hand, a number of these children complaining similarly did have acute appendicitis but also developed pneumonia afterward. It seems to me that they must have had more or less of a general infection, appendicitis, and the chest condition at the same time. Then again, I have operated on a few expecting to find appendicitis (though I was not sure whether the condition was pneumonia or acute appendicitis), and found that these children had acute appendicitis, but this group never developed any chest symptoms or any evidence of pneumonia afterward.

I do not know whether there is any way of making an absolute differentiation between an acute appendicitis in a child in its first attack and the beginning of pneumonia. I think most of them must have an abdominal infection and a lung infection at the same time. Of course, we do not like to operate on a child with pneumonia, but the risk of permitting the condition to develop into suppurative appendicitis and peritonitis, we all know, and Dr. Helmholtz' figures show the danger of that.

A point regarding the surgical aspect of this condition. It seems to me that the infections in children are more virulent than in adults. Ordinarily, we feel that it is safe to wait forty-eight hours in adult cases and at operation still expect to find the trouble confined to the appendix, but I have seen a great many children where the appendix has ruptured in twenty-four hours. With adults, we have adopted to a large extent the treatment suggested by Ochsner, thus assisting the patient to wall off the infection with the idea of later establishing drainage, and making an appendectomy. I believe that we should operate on cases of acute appendicitis in children at the end of the second day, even if we feel that the appendix has ruptured. The peritonitis may not be diffuse. I feel sure that our results would justify this procedure.

Another question that Dr. Helmholtz brought up in his paper, interested me: should the child be operated on after having had only one attack? I think we should operate, if the diagnosis can be made. I also wanted to emphasize the point that he made in saying that the most important single factor in the diagnosis of acute appendicitis in children is local tenderness. It requires some little time to get the confidence of the child before one can get anything as to the difference in resistance in the abdominal muscles. I have been very much interested in watching the pediatricians in just this particular in their contact with children and realize that after gaining confidence this sign becomes most valuable.

DR. ROY ANDREWS, Mankato Clinic, Mankato, Minn.: We know that pyelitis in younger children is generally without any definite symptoms but pyelitis in older chil-

dren may have definite manifestations. I recall two cases we had of children over six years of age that were brought in with a diagnosis of appendicitis made by the parents themselves. They had severe pains in the right side, intermittent in character but with an absence of local tenderness which we would expect in a child of that age. The urine of these children was loaded with pus and some blood. We must remember that pyelitis is not so easy to diagnose, that is, the first specimen of urine does not always tell us the story. Many times it will take three or four specimens of urine before one finds pus.

Another condition that has puzzled me and will continue to puzzle me is retrocecal appendicitis in children. Usually they are difficult to diagnose because the tenderness and spasticity come on rather late. I think it is very difficult to make an early diagnosis of retrocecal appendicitis.

DR. T. L. BIRNBERG, St. Paul: It has given me great pleasure to be here today and hear this paper. The subject of appendicitis in children has been a thing that has puzzled me a great deal. You always hear the surgeons talking about operations for appendicitis but I must confess in our work we have had very few appendices. I often wonder if we have had them and were not able to diagnose them. The differential diagnosis is one of extreme importance, and as Doctor Judd said we must gain the confidence of the patient and slowly make our diagnosis. I get considerable benefit by asking the child to himself show me where his pain is. After he shows with the palm of his hand, as he always will, I ask him: "Please, with your one finger show me the place that it hurts." Now: "Which place does it hurt the worst?" Meanwhile talk with him about school, the school teacher, and things of that nature and get his mind on different things. Gradually his fear will relax and you get what you are after.

There are two things in differential diagnosis of great importance, pyelitis and pneumonia. Those must be ruled out in every case before operation. I make it a rule that no patient should be operated for appendicitis before a urinary examination is made and an x-ray of the chest. Surgeons are very prone, when they examine a patient and find pain in the side and temperature, to say: "We will take out the appendix right away." These findings are very good and very accurate in adults but in children they are misleading and we are not willing to take the risk in doubtful cases. It is better to be safe and operate an hour or two later than to operate on a pneumonia case. We have seen a good many other pneumonias after appendices through mistaken diagnosis.

The question of diarrhea. In adults constipation is the rule in appendicitis cases but it is not unusual in children to have loose bowels and very small, frequent stools. Small, frequent stools are a little unusual in infants in appendicitis. The high temperature often worries a surgeon, he will be afraid of 103 and 104 Fahrenheit. I must confess that whenever a high temperature is presented I think first of pyelitis or pneumonia and appendicitis last. Do not pay too much attention to high temperature in children, because it might be run in an effort of thermotaxis. The temperature will suddenly go high without great cause, as well as the leukocyte count. The leukocyte count in children may go up very high without being of much consequence.

THE CHAIRMAN (Dr. H. Z. Giffin, Rochester): Anything that will assist in the diagnosis of appendicitis in these very young children it seems to me is most important. I am afraid that the rectal examination is apt to be neglected in young children. In appendicitis a sensitiveness in the right lower quadrant by rectal bimanual examination can almost always be elicited; moreover, a pelvic abscess is not infrequently detected by this method when abdominal symptoms are confusing.

DR. R. C. LOGEFEIL, Minneapolis: I am reminded of a case in which I was called in consultation, a short time ago. It was a child about ten years of age who had been running a temperature of about 103 in the evening for the past three or four days. At times the child complained of some pain in the abdomen but there was no nausea or vomiting. When the surgeon had seen the case the temperature was normal and the leukocyte count somewhere between 15,000 and 20,000. On account of absence of tenderness and rigidity in lower right abdomen, he made a temporary diagnosis of a central pneumonia and advised an x-ray. I was called in to see the child the next morning and found that the x-ray was negative as well as the urine examination, the latter ruling out a possible acute pyelitis.

On examination I found the child complained mostly of pain in the lower part of the right chest especially when taking a deep breath. I followed Dr. Birnberg's hint, which I learned when I was under him at the City and County Hospital, by asking the child to show me the exact point of tenderness with one finger. She could not do this as it seemed to hurt over the entire lower chest and upper abdomen on the right side. I am frank to say I did not have the nerve to make an exact diagnosis of anything but I believed on account of the definite rigidity and slight tenderness in the upper right quadrant, that there must be an acute abdominal condition present, and advised operation.

Another surgeon was called in consultation after I saw the case and he, for no reason that I could see, unless he had more nerve, diagnosed an acute pus gall-bladder and the case was operated half an hour later. I had the opportunity of witnessing the operation and saw the surgeon reveal a long retrocecal gangrenous appendix which extended upwards toward the liver with a ruptured tip and an abscess just below the gall-bladder. There was a localized peritonitis with a hepatitis and I assume an inflammation of the peritoneal surface of the diaphragm which accounted for the pain on breathing. I certainly can agree with those who have spoken before me, namely, that the diagnosis of acute appendicitis in children is often very difficult.

DR. H. T. HELMHOLZ, Rochester (closing): I want to emphasize again what Dr. Judd has said about the difficulties of the differential diagnosis of pneumonia and appendicitis and to say that I think it is better to operate on an occasional pneumonia, thought to be appendicitis, than to let an acute appendicitis go to generalized peritonitis.

With regard to pyelitis, I must confess that I have never encountered this difficulty; I suppose because of my interest in pyelitis that is always the first thing I think of. The only case in that connection that we did have difficulty with

was an acute hydronephrosis, in differentiating it from an acute appendiceal abscess.

Another thing that I would like to emphasize in connection with the differential diagnosis of pyelitis and appendicitis is the value of a catheterized specimen and the presence of bacteria at a time when pyuria is not present. I think particularly in these early cases one might find a urine swarming with bacteria when there is no pus and it be of great help in the diagnosis.

In conclusion I want to thank those who have discussed this paper in bringing out in detail some of the points I could only lightly touch on.

But it is a secondary matter, after all, whether a school is under State or University control, whether the endowments are great or small, the equipments palatial or humble; the fate of an institution rests not on these; the inherent, vital element, which transcends all material interests, which may give to a school glory and renown in their absence, and lacking which, all the "pride, pomp, and circumstance" are vain—this vitalizing element, I say, lies in the men who work in its halls, and in the ideals which they cherish and teach. There is a passage in one of John Henry Newman's Historical Sketches which expresses this feeling in terse and beautiful language: "I say then that the personal influence of the teacher is able in some sort to dispense with an academical system, but that system cannot in any way dispense with personal influence. With influence there is life, without it there is none; if influence is deprived of its due position, it will not by those means be got rid of, it will only break out irregularly, dangerously. An academical system without the personal influence of teachers upon pupils, is an Arctic winter; it will create an ice-bound, petrified, cast-iron University, and nothing else."

Naturally from this standpoint the selection of teachers is the function of highest importance in the Regents of a University. Owing to local conditions, the choice of men for certain of the chairs is restricted to residents in the University town, as the salaries in most schools of this country have to be supplemented by outside work. But in all departments this principle should be acknowledged and acted upon by trustees and faculties, and supported by public opinion—that the very best men available should receive appointments. It is gratifying to note the broad liberality displayed by American colleges in welcoming from all parts teachers who may have shown any special fitness, emulating in this respect the liberality of the Athenians, in whose porticoes and lecture halls the stranger was greeted as a citizen and judged by his mental gifts alone. Not the least by any means of the object lessons taught by a great University is that literature and science know no country, and, as has been well said, acknowledge "no sovereignty but that of the mind, and no nobility but that of genius." But it is difficult in this matter to guide public opinion, and the Regents have often to combat a provincialism which is as fatal to the highest development of a University as is the shibboleth of a sectarian institution.—From *Teacher and Student*, William Osler.

THE MORE COMMON NEUROLOGIC DISORDERS ASSOCIATED WITH PAIN, AND ENCOUNTERED IN GENERAL DIAGNOSIS*

HENRY W. WOLTMAN, M.D.

Section on Neurology

Mayo Clinic, Rochester, Minnesota

Although the medical profession, in general, casts an indifferent or a scornful eye on the pagan subject of neurology, the fact remains that no less than 10 per cent of patients examined present some neurologic symptoms or aspects that enter into the general diagnosis. This is particularly true of nervous disorders associated with pain. The spread of an impulse to every part of the neuron provides many pitfalls in diagnosis, and disappointment for the surgeon who finds that the disease refuses to respond to the rites employed to banish it.

Fig. 1. Diagrammatic survey of nervous disorders that often enter into differential diagnosis.

In the process of diagnosis it is customary to visualize such structures as the liver and the stomach, but the nervous system is habitually disregarded, a practice which sooner or later leads to difficulties that might have been obviated had some such simple diagram, as is represented in Figure 1, been kept in mind.

Lesions within the substance of the brain or spinal cord, while at times associated with pain, do not lead to diagnostic difficulties sufficiently often

*Presented before the Medical Section of the Minnesota State Medical Association, St. Paul, Minnesota, October 10-12, 1923.

to warrant extensive discussion.¹ An exception must be made with regard to tumors of the brain, extracranial neoplasms, such as nasopharyngeal malignancy, and various neuralgic and painful disorders around the head for which optometric, nasal, and dental manipulations are often instituted. However, attention is here directed more particularly to root pains, and to abdominal crises, the origin of which is probably in the vegetative nervous system.

ROOT PAINS

Root pains are often erroneously interpreted as intercostal neuralgia, pleurisy, pericarditis, appendicitis, cholecystitis and kindred abdominal conditions, lumbago, and sciatica. They usually present characteristic features, most typically seen in pressure from spinal cord tumors, that should lead us to suspect the possible nature of the lesion, al-

though the ultimate proof may be very difficult. Table 1 illustrates the salient features of root pains and the points of contrast and similarity as applied to sciatic neuritis, with which it is often confused.

ILLUSTRATIVE CASES

Case 1 (A438405). *Spinal cord tumor with pain leading to multiple operations.* Mrs. C. S., aged twenty years, complained chiefly of pain in the right lumbar and abdominal areas. One and one-half years before, a dull ache appeared to the right of the second lumbar spine, radiating laterally to the lower costal margin. The pain was more constant at night and caused the patient to sleep in a chair. Fourteen months before, the appendix and part of the right ovary had been removed without relief; eight months before, the pain radiated to the right knee, and a cast was applied to the leg for several weeks. Four months before, the remaining portion of the right ovary was excised without benefit.

The patellar and tendo achillis reflexes were slightly

TABLE 1.

THE MORE CHARACTERISTIC FEATURES OF ROOT PAINS AS COMPARED WITH THOSE OF SCIATICA

	ROOT PAIN	COMMON TO BOTH	SCIATICA
Location:	Anywhere. Referred to peripheral distribution of neurone. At first unilateral, later bilateral (girdle) and symmetrical.	May be same.	Buttock, posterior aspect of thigh, calf. Rarely bilateral.
Character:		Usually dull ache.	
Onset:	Gradual.		Often acute, especially after strain, exposure or "cold."
Course:	Continuous or recurrent. Spreading to contiguous territory, especially to opposite side; growing in intensity.	Reappearing at intervals. Worse on coughing, sneezing, straining.	First attack often the worst. Field of activity unchanged.
Tenderness:	None.		Present at nodal points.
Flexion of head:	Aggravates pain.		No change.
Kernig and Lasègue:		Present, especially if tumor is low.	
Spine:	Often fixed.	Listing common.	
Temperamental idiosyncrasies:	Without pain on retiring; awakened at 3:00 a. m. by pain, relieved by kneeling or exercise. Returns to bed toward morning. Often prefers to sleep sitting in chair.		Often kept awake by pain on retiring. Pain wears off gradually, allowing patient to sleep. Worse on exercise. Worse on sitting in chair.
Weather and temperature influence:	None.		Often striking. Pain worse on cold, relieved by heat.
Neurologic findings:	Sensory, motor, reflex, and spinal fluid.		Tendo Achillis reflex often absent in severe cases. Nodal tenderness. Positive Lasègue.

more active than normal; positive Babinski reflex was present on the right, a doubtful one was noted on the left. Vibration and joint sensibility were slightly impaired over the right lower extremity. There was slight urinary urgency. The spinal fluid was straw colored, the Nonne reaction was positive, there was one lymphocyte, zone I colloidal benzoïn reaction, and no fluctuation on jugular pressure. An extramedullary cord tumor was removed from the anterior aspect of the seventh thoracic segment.

The appearance of this patient did not indicate any abnormality of the nervous system. She walked without difficulty, was aware of no disturbance of sensation, and suffered no impairment of sphincter control. The story of characteristic root pain, however, at once suggested the possibility of a spinal cord tumor. (Fig. 2.)

Fig. 2. Case 1 (A438405). Spinal cord tumor with pain leading to multiple operations. The general appearance of this patient did not indicate any abnormality of the nervous system. (The Arabic numerals refer to tactile sensibility, the encircled Arabic numerals to pain sensibility, and the Roman numerals to temperature sensibility. 0 signifies normal, and -4 complete loss, intermediate figures representing intermediate degrees. The plus sign represents increase, +4 being the maximum.)

Case 2 (A386055). *Caudal tumor masquerading as sciatica for ten years. Hypertrophic arthritis.* Mr. J. C. McL., aged fifty-two years, had developed a dull pain in the left sacro-iliac region, thigh, knee, and calf, ten years before examination at the Clinic. The pain was worse at night and was relieved by exercise, so that the patient often worked at night. There was no relation to changes

in the weather. Five years before, his teeth had been extracted and tonsillectomy performed without relief. Three years before, the pain extended to the right side of the back and down the right leg, so that he was unable to lace his shoes. The pain disappeared for two years following the administration of laudanum and salicylates by rectum, and changing the style of shoes. For the last thirteen months the pain had been worse and the patient used morphin daily. He never missed his work.

The Lasègue sign and Nonne test were positive. Hypertrophic arthritis of the lower dorsal spine was diagnosed roentgenologically. A neurofibroma was removed from the level of the second lumbar vertebra.

The objective neurologic findings included only the positive Lasègue and the positive Nonne tests. It was largely on the basis of the history that this patient was explored for a caudal neoplasm. The

Fig. 3. Case 3 (A380470). Caudal tumor simulating sciatica.

hypertrophic arthritis, which was observed in this case, is commonly associated with cord tumors, and often confuses the diagnosis.

Case 3 (A380470). *Caudal tumor simulating sciatica.* Mr. W. S., aged thirty-five years, complained of sciatica. Three and one-fourth years before, he had contracted flu,

and during the attack remained in a shack without food for one and one-half days, the temperature being 36° below zero. Following this, severe pain appeared in the lumbar spine, left hip and thigh. The pain occurred more often at night, when the patient slept in a chair, or obtained relief by walking. He could "tell when the sun set and when it rose" by the intensity of the pain. There was no relation to the changes in the weather. For two months he had had a constant tingling sensation along the outer surface of the left thigh.

The patient listed to the right. Flexing the head caused an increase of the pain in the left leg. The Lasègue sign was positive. The left tendo achillis reflex was absent. There was marked impairment of tactile sensibility and slight impairment of pain and temperature sensibility over the posterior aspect of the left leg and the lateral aspect of the foot (Fig. 3). The first, second and third lumbar spines were tender. The Nonne test was positive, and there were seven lymphocytes. Chondrofibroma arising from the third sacral intervertebral disc was found at operation.

Root and nerve trunk pains are often one of the earliest indications of a malignant process. In the search for a possible primary focus, a rectal examination, the elimination of the possibility of a primary carcinoma of the lung, and inspection of the nasopharynx should never be neglected. Involvement of the posterior root ganglia is well exemplified in herpes, which may be followed by a post-herpetic neuralgia. Doubtless a ganglionitis is not always evidenced by vesicle formation, and presumably a typical herpetic neuralgia may develop without the preliminary appearance of vesicles.

GASTRIC AND ABDOMINAL CRISES OF NEUROSYPHILIS

Gastric and abdominal crises are almost always an expression of parenchymatous syphilis of the central nervous system, but may be associated with migraine, angioneurotic edema, and unknown causes in apparently healthy persons. Crises are usually typical and present certain characteristics. The onset is sudden, with pain or vomiting, usually both, but either may occur singly, or there may only be flatulence, extreme nausea and sialorrhea. The pain is usually near the middle-line, and symmetrical; it may be dull, sharp, aching, cramping, squeezing, gripping, burning, or numb in character. The intensity may be mild or grewsome, and the duration from a few hours to several days. The pain is rarely continuous, and ceases suddenly. There is no interval abdominal complaint, unless the condition is complicated as by ulcer. The crises are recurrent, and the intervals vary widely. There is no tenderness to deep pressure, but there may be

marked hypersensitivity to light touch, and objective evidence of syphilis is usual.

Of 120 patients with syphilitic gastric crises, thirty-one (25.8 per cent) were operated on. (Table 2.)

TABLE 2

OPERATIONS IN 120 CASES OF SYPHILITIC GASTRIC CRISES	
Appendectomies	20
Operations on gallbladder.....	14
Operations on stomach.....	12
Operations on pelvis (ovaries removed in five cases, tubes in one, suspension in one).....	8
Operations on kidneys (Dietl's crisis one).....	3
Adhesions	3
Exploration	2
Reduction of colon.....	1
Total	63

ILLUSTRATIVE CASES

Case 4 (A334732). *Gastric crises of tabes: multiple operations.* Mr. G. D., aged thirty-six years, had had specific urethritis, and possibly syphilis, at the age of twenty years. At the age of twenty-nine he experienced his first gastric crisis, which awakened him at 2:00 a. m.; appendectomy was performed at 5:00 a. m. At the age of thirty-one an operation was performed for adhesions, and one year later a gastro-enterostomy; four years later 15 cm. of "kinked ileum" was resected, with return of another crisis before the patient left the hospital. The attacks were grewsome in their intensity, and reduced the patient to a groaning, quivering heap.

Examinations were negative except for positive Wassermann and Nonne reactions, and 18 lymphocytes to a cubic millimeter of spinal fluid.

Case 5 (A374807). *Gastric crises of tabes: multiple operations.* Mrs. C. H., aged thirty-seven years, had had typical gastric crises five years before. At the same time the right eye deviated outward with subsequent diplopia. Four years before, the appendix had been removed without relief; the gallbladder was then drained with similar result, and subsequent gastropexy proved unavailing.

Right ptosis, complete bilateral external rectus paralysis, irregular and Argyll Robertson pupils, absent patellar and tendo achillis reflexes, very active abdominal reflexes, and reduced muscle tenderness were noted. The serologic examination was negative.

The abdominal scars testify to the splendid resilience of this tabetic patient. The complete right sided ptosis, the bilateral external rectus palsy, the irregular, Argyll Robertson pupils, the absent patellar and tendo achillis reflexes had no restraining influence on the persistent endeavors of surgical research to disclose some point of visceral strategy from which these symptoms seemed to emanate. (Fig. 4.)

Case 6 (A273093). *Gastric crises of tabes: multiple operations.* Mrs. W. J. S., aged fifty years, had contracted syphilis thirty years before. For the last four years she

had suffered greatly from "rheumatic" lightning pains and attacks of abdominal pain associated with vomiting. Two years before she was temporarily blind in both eyes. Eleven months before, an operation had been performed on the gallbladder, and two weeks later a nephropexy was performed, both without relief.

Unequal and Argyll Robertson pupils, left optic atrophy, absence of right patellar reflex, diminished left tendo achillis reflex, absence of muscle tenderness, marked delay in pain sensibility, positive Wassermann reaction on the spinal fluid, and 36 lymphocytes to the cubic millimeter were noted. (Fig. 5.)

Characteristic objective findings of parenchymatous neurosyphilis. Case 6 was introduced in order

Typically they are sharp in character; short in duration, as though the patient had been shot through the leg or touched with a lighted cigarette; spot-like more often than lightning-like, so that the painful spot might be covered easily by a silver dollar; severe or mild in intensity; they appear in showers, are present usually in the lower extremities, are not limited to the regions of joints, and may leave the skin hypersensitive to light touch, but not to heavy pressure.

Fixed pupils or even Argyll Robertson pupils, which react to accommodation, but do not react to

Fig. 4. Case 5 (A374807). Gastric crises of tabes. Multiple operations. The abdominal scars testify to the splendid resilience of this tabetic patient.

Fig. 5. Case 6 (A273093). Gastric crises of tabes. Multiple operations showing characteristic objective findings of parenchymatous neurosyphilis.

to show some of the very characteristic objective findings of neurosyphilis. A closer analysis of the "rheumatism" revealed typical lightning pains. Formerly as many as seventy-five kinds of pain were differentiated. Today very few are considered characteristic of an illness. Lightning pains are almost pathognomonic of parenchymatous syphilis of the central nervous system; they rarely occur in cases of diabetic multiple neuritis, syringomyelia, or in healthy persons, without demonstrable cause.

light, are no longer considered pathognomonic of syphilis. They may be present with epidemic encephalitis, and may be familial, although rarely. If they are unequal and irregular as well as Argyll Robertson, they usually indicate syphilis. A diagnosis of neurosyphilis, however, should never be made on one sign alone.

The patient in Case 6 also had a chest zone of diminished sensibility, which may involve any quality of superficial sensation. Oppenheim re-

lates the case of a woman who in the course of a banquet pinned a flower to her waist, passing the pin through the underlying breast. She was unaware of this until she discovered the fact on undressing that night. While a chest zone may occasionally be noted in other nervous diseases, such as in syringomyelia, it is ordinarily strong evidence of syphilis. In this case, furthermore, pain sensibility was delayed longer than touch sensibility in the feet; when the feet were pricked with a pin, the patient perceived the touch of the point before she felt the pain. This delay is seldom noted in any disease other than parenchymatous neurosyphilis.

Finally, there was an absence of normal muscle tenderness. When one of the bellies of the gastrocnemius muscle is pinched firmly, the patient normally gives lively evidence of pain. When this tenderness is absent in the presence of voluntary movement or fairly intact cutaneous sensibility, the possibility of syphilis should suggest itself at once. In multiple neuritis the tendon reflexes are often absent as they sometimes are in tabes, but in the former, muscle tenderness is exquisite, while in tabes it is often greatly impaired or absent.

ABDOMINAL CRISES OF NON-SYPHILITIC ORIGIN

Abdominal crises are not alone seen in cases of parenchymatous syphilis. The patient in Case 7 obviously had syphilis, but the appearance of the crisis evidently antedated the syphilitic infection.

ILLUSTRATIVE CASES

Case 7 (A328858.) *Abdominal crises (migraine? syphilis?)*; *multiple operations*. Mrs. J. H., aged forty-six years, had had periodic headaches since the age of twelve years; at the age of twenty-three, abdominal pains were associated with the headaches. The pain was most severe in the right upper quadrant, was continuous, sharp and cutting, and associated with vomiting; it lasted about six weeks. The patient had lost 75 pounds in weight. Morphine was required for relief. She was married at the age of twenty-eight. Eight years before examination, she had developed unsteadiness in walking, girdle pain, hyperesthesia of the abdomen to cold and heat, lightning pains, incontinence and impaired vision. Five years before, the gallbladder was explored and found to be negative. The patient's mother had had migraine headaches with vomiting; one brother had had abdominal crises of pain without vomiting or headache ever since he was eighteen; another brother had had intense abdominal crises of pain and vomiting with headaches since the age of eighteen; and one son had abdominal crises of pain, with or without vomiting, but always with headache.

Nystagmus to the right, unequal, irregular, Argyll Rob-

ertson pupils, absence of the right patellar reflex, slight ataxia, slight impairment of joint sensibility in the toes, absence of vibratory sensibility over and below the pelvis, impaired tactile sensation with localized hyperhidrosis over the fourth dorsal segment on the right, marked impairment of pain sensibility, and slight urinary incontinence were noted. The serologic examination was negative. (Fig. 6.)

Fig. 6. Case 7 (A328858). Abdominal crises of migraine (?) in a patient having tabes.

Abdominal migraine. Buchanan has discussed the abdominal manifestations of migraine, and Moersch has emphasized the protean expressions of this disorder. The existence of abdominal migraine is not only questioned, but openly ridiculed in certain quarters. This attitude calls to mind the story of Francisco Sizzi, a Florentine astronomer, who argued against Galileo's discovery of a new planet in the following manner: "There are seven windows in the head, two eyes, two ears, two nostrils, and a mouth" (which we may paraphrase by saying, the appendix, the stomach, the gallbladder, and so forth). "From which, and many similar phenomena in nature, such as the seven metals, the seven days of the week, and so forth, which it were too tedious to enumerate, we gather that the number of planets is necessarily seven." The abdominal crises of migraine are particularly interesting,

since the diagnosis depends entirely on the history of the case.

Case 8 (A278573). *Appendectomy and abdominal exploration without relief.* Miss E. H., aged twenty-eight years, had begun at the age of twelve years to have attacks of black spots before the eyes for five minutes, blindness for three-quarters of an hour, aphasia three and three-quarters hours, intense headache for from two to four hours, followed by abdominal pain of four to five hours' duration (at times so intense as to require morphin for relief), and continuous vomiting, without pain, for from three to four days. At the completion of the attack, a watery evacuation of the bowels occurred. The headache stopped at the age of seventeen, but the abdominal attacks continued. At the age of twenty-four appendectomy was performed, and four years later a negative abdominal exploration, without relief. The family history was negative.

Detailed examination, including full investigation for syphilis, was negative.

Case 9 (A245593). *Asthma; angioneurotic edema; local syncope, and duodenal ulcer.* Mr. H. C. S., aged fifty years, had had attacks of abdominal pain since the age of sixteen, coming on about four times a year, and of three or four hours' duration. The pain was intense, epigastric, accompanied by nausea and vomiting, and relieved somewhat by pressure. Attacks were always introduced by brilliant, scintillating scotomas followed by blindness. There was no headache. The patient also distinguished other types of pain, evidently related to duodenal ulcer. His mother had had attacks of "terrific abdominal pains" associated with blindness and vomiting of from three to four hours' duration, coming on about twice a year for ten years. A brother had similar attacks. One sister and one brother suffered from severe attacks of migraine headaches. For the last seven years the patient has had attacks of asthma, and for the last year angioneurotic edema, the swelling persisting for three days at a time. There were also local syncopal attacks involving the fingers. The asthma, edema, and blanching were not familial.

All skin tests were negative. There was fluctuating eosinophilia from 15 to 55 per cent, with 16,000 leukocytes. The diastolic blood pressure was 92, the systolic 60. Roentgen-ray examination revealed a duodenal ulcer. Pleurisy, adhesive pericarditis, slight fatty changes in the liver, thickened walls of the gallbladder, one healed gastric ulcer, and one active duodenal ulcer were found at necropsy.

Most patients with abdominal crises of the migraineous type have had at least one abdominal operation with negative results.

Abdominal disturbances associated with brain tumors. In some instances the vomiting and abdominal discomfort associated with brain tumors have led to operation on the abdomen. This is particularly true of fourth ventricle tumors.⁵ The abdominal distress complained of by these patients is possibly vagal in origin.

Vascular disturbances of the peripheral vessels may be associated with intense pain and anesthesia. This is particularly true of thrombosis or embolism of the vessels producing ischemia or infarction neuritis. Palpation of the vessels helps to establish the diagnosis.

Pain in cases of amputation-neuroma is many times central in origin and cannot be relieved by incision of the neuroma, injection of the plexus, or section of the posterior roots. Needless to say, in these cases of psychalgia, peripheral operations only aggravate the pain.

Pains of hysterical origin. We often fail to acquaint ourselves with the endeavors of mental analysis and mental hygiene. Our mental and emotional operations have no limitations. Like the philosopher's description of the universe, they are like a huge sphere whose center is everywhere and whose surface is nowhere. That we must be on the alert constantly is illustrated by the case of a woman who came to a physician complaining of pain in her side, for which her appendix was removed. Pain in both hands and in both feet, which she insisted on talking about, was disregarded. She later confided, with ecstasy, that she was Christ crucified. The diagnosis of hysterical conditions is, however, seldom so transparent, and we all contribute amply to the monumental blunders committed in this field.

Case 10 (A402420). *Hysterical pain and paralysis of foot, of six months' duration, treated as a tuberculous ankle.* Miss A. A., aged seventeen years, had tripped on the school stairs and sprained her right ankle six months before coming to the Clinic. The doctor who was called shook the foot roughly and told her to use it. Following this, the foot became extremely painful, and she could not move it. Another physician applied a cast for three weeks, with no improvement. The condition was diagnosed tuberculosis of the ankle and an operation discussed.

There was loss of voluntary movement of the right leg and foot, "exquisite tenderness," and emotional lability. The patient's father had died recently, leaving a large family without resources. Her mother was a "crêpe hanger." The patient was much hurt by the lack of sympathy on the part of the first physician, greatly impressed by the extreme solicitude of the second, by the cast, and by the prospect of operation. She recovered under treatment by suggestion and faradism.

Case 11 (A432880). *Hysterical dyspraxia and pain.* Mrs. F. M., aged thirty-four years, complained chiefly of pain and disuse of the right arm and fingers, pain in the right abdomen, hip, knee, and spine. The "whole right side was bad." Five years before, much to her distaste, but compelled by circumstances, she had taken a stenog-

rapher's course. While doing this, a dull pain appeared in the right hand which drew away from its task involuntarily on every effort to use it; she felt as though the fingers were torn out at the roots. The patient became nervous, had spells of crying, shaking, universal numbness and rigidity with loss of speech and movement, but retention of hearing. She was given hypodermic injections of morphin almost daily because of abdominal pain, for a period of two years. She was told that the right ovary was diseased. Three and one-half years before coming to the Clinic, tonsillectomy had been performed, and three years before, appendectomy, without relief.

The objective examination was negative, except for obviously hysterical dyspraxia in the use of the right hand, shifting areas of tenderness, and excessive emotional lability. The patient had married first at the age of sixteen; she gave birth to a daughter at the age of eighteen. The husband was drowned when the patient was twenty years of age. She was married a second time to a young man whom she loved, but whom she left because he did not support her. (This marriage was kept secret until discovered through a dream the patient related.) The stenographic course was taken at the age of twenty-nine. She could not earn her living and failed at five positions. She married a wealthy bachelor, aged fifty-six years, for whom she did not care. This man was extremely jealous, and encouraged the patient's undisciplined daughter, aged sixteen years, to marry a shiftless wretch many years her senior. The patient had often dreamed that she saw a recent picture of herself, which stands framed on her husband's dresser, replaced by one taken before her third marriage, when she was a beautiful young woman. A very common dream is that the patient is walking along the street when she is accosted by a very handsome young man (her second husband) who asks for her telephone number. At this moment a horrible old man, all covered with long black hair, jerks her away and threatens to arrest her for talking to a stranger. (The striking thing about her present husband is his "beautiful long black hair.") She declares her innocence. In a recent dream, the patient, with the assistance of a young doctor, is shaking a bowl of urine on which is floating a greasy substance.

Popular misconceptions, and sometimes even physicians, are responsible for the development in patients of an anxiety neurosis, from which they suffer more intensely than from the disease. Such anxiety is often aroused inadvertently by the physician's silence, or by implication of a diagnosis not yet justified or possible. Much harm and seldom good may be done by adding the element of fear. One patient, having long since recovered from his physical illness, felt that he must continue being ill and unable to work because he had been told that he would be so for about four years. A bugaboo too often attaches to the following diagnoses, leading to unnecessary invalidism: pre-incipient tuberculosis (compare the good morale, lack of fear, and co-operation of patients who know

they have the disease, in sanitariums); high blood pressure, will be dead in a year; heart disease; cancer, which they have not; Bright's disease; masturbation (when the Sunday school teacher, reformer, and quack too often advise gratuitously; unfortunately the doctor is seldom consulted). There are more suicides on bright sunny days than on cloudy days, and there are almost no suicides during catastrophes. Our patients' fears, self indulgences, and complexes should be discovered, removed, and replaced by common sense and a robust philosophy.

The neurologic conditions most often missed in diagnosis, and which consequently lead to abdominal operations are: gastric and abdominal crises, usually syphilitic; root pains, usually in cases of cord tumor; vomiting due to cerebral lesions, especially tumors of the fourth ventricle, when associated with abdominal distress; hysteria or family traditions, such as "Brown's stomach"; and constitutional somatic deficiency, and biologic inferiority.

Neurologic diagnoses too frequently made are neuritis (for root pain, referred pain, myositis, bursitis, vascular disturbances, especially thrombosis and embolism); neuralgia, especially the rare condition of intercostal neuralgia; functional disorders, for example, telegrapher's cramp, to explain pain; and syphilis of the nervous system. These errors are seldom due to inadequate knowledge in a special field, but usually find their source in faulty histories, and in the attempt to treat the patient's body to the neglect of his mind. As Seneca said centuries ago, "The two blessings of life are a sound body and a quiet mind."

DISCUSSION

DR. ARTHUR S. HAMILTON, Minneapolis: Doctor Woltmann has just given us a very well prepared and carefully considered paper, as he always does. I am glad that he particularly emphasized the question of root pains. I think

root pains are not well enough understood, not enough attention is ordinarily paid to them. I suppose that pain is the most common complaint with a patient; certainly it is in neurologic lesions. The patient comes complaining of some kind of pain or distress from which he or she wishes relief. In a general way there are two classes of pain, perhaps not very clearly divided in fact, much less in our minds, but in a general way we think of pain as due to an organic situation and pains of functional origin. Under functional we may include cases where the patient complains, such as malingerers who pretend they suffer pain although they do not.

There is something more or less characteristic in the way people present their complaint of pain. A man who has a pain of organic origin will locate it always in the same spot. He has no particular difficulty in telling you where it is and he outlines it clearly. If he has any occasion to speak of it or to return to it under different points of his examination he gets it about the same; whereas it is really very striking how functional pain is always complained of at some one point in the examination as very severe, and yet you come around some time later in the examination to the same part and the same part of the story and somehow the pain seems to have been moved.

A man who has an organic pain can usually outline it clearly; if you ask him where the pain is he can outline it clearly with his finger; but the man who has a functional pain is very much more likely to pass his hand loosely over some part of the body and say: "It is about here." I was reading an article the other day by Dr. Spellman and Dr. Fraser of Detroit, on a series of cord tumors, and I noticed a striking thing. They took a considerable series of cord tumors such as came back over quite a period of time, and the average time from the onset of the first symptoms that were more or less suggestive of what the trouble might be until a diagnosis was actually reached was 2.5 years, which seems a rather long time, I think a longer time than is necessary.

I remember one of those cases particularly; Doctor Woltmann knows the case because he deserted me later on and went to him. A man had had an operation for gallstones. As far as I could find out there was a pretty vague statement of what was found at the operation. He had a definite pain in the region of his gallbladder, to be sure. Just exactly why the pain should have gone away after the operation I don't know, but he said it did. By and by it came again and he went to another surgeon. He was operated upon for gallstones and this time it is clear that no gallstones were found. He was better for a while. Then he went to a third surgeon and he had a terrific pain in the gallbladder but, strange to say, he had this pain on the left side. I saw him and diagnosed it very quickly. Not only had he had the pain, the root agitation, but the thing had gone on so far that he had developed a definite numbness on the right side. Afterwards Doctor Woltmann informed me that they found a spinal tumor on this side and the man was relieved.

Root pains that occur in such cases as tumors of the cord are pretty suggestive from the beginning. I do not mean one can make a diagnosis of spinal tumor on the

basis of root pains appearing, but if the root pain appears in a definite region or is continuous, it may vary somewhat in degree but it is sometimes continuous and always in the same region it is at least a suggestive symptom. Then if there comes a pain on the opposite side of the body at the same level, it becomes a very suggestive thing, and here one should make a diagnosis as one sees the product so very clearly of a transverse myelitis of the cord substance due to some infection. When a man has a perfectly clear picture of a root pain on one side and a subsequent root pain on the other side, and after having such a situation lasting several months until the man becomes paralyzed, that syndrome does not suggest a myelitis at all, it suggests a pressure lesion on the cord.

There are other methods by which one may diagnose absolutely the actual organic pain from those of functional origin. As to malingering pain, if you do anything in the course of your examination which is supposed to bring on the pain severely and you have been observing the patient's pulse and you find there is no rise of the pulse at the time when you were supposed to be hurting him pretty severely, it is pretty positive evidence that the pain is not a pain of organic origin. That is the case particularly in the back, where so many patients complain of pain, and there is no contraction of the muscles. They remain relaxed throughout the examination and you have grave reason to doubt whether the thing is of organic origin. As I said before, it is rather striking how people will complain bitterly of a painful place of some sort in connection with their illness at one stage of the examination and you go on with the examination and come back to the same pain and the patient has apparently forgotten about the matter or if he has not wholly forgotten it he describes it in a different way and locates it in a different position.

Of course, it is well known that some people bear pain very much better than others. Some people complain a great deal of a small matter while others complain but little in a very serious matter. The question of numbness—I don't know as we can speak of this as a pain but it belongs in the field of sensation. It is widely known that patients who mangle in respect to total loss of sensibility almost always fail to make their loss of sensation in any way comply with the known sensation of the part, and he cannot even keep the limits of his loss of sensibility at the same point. The man is unable to outline things as they were before when you come back to your question. In situations of that kind we find a certain sense derived from experience that leads us to believe that the man is not dealing honestly with you in these cases of malingering.

I think there is another way in which you can distinguish real from simulated pain. If it is real pain and you touch anywhere near the affected part you get practically an instant response, but in the other case, as you recur to the area from time to time, you will find that it takes an effort of the memory of the person to evince pain and there is an appreciable interval of time before he registers pain.

DR. L. A. NIPPERT, Minneapolis: Before considering pain as a manifestation of a neurological disorder and re-

ferring our patient to the neurologist for treatment we should remember that its origin may be distant from the subjective location as the following cases which came to my mind as I listened to Dr. Woltmann's interesting and exhaustive paper will show:

CASE 1: A woman previously healthy taken with severe griping pain in the pit of the stomach with nausea and vomiting. Examination of abdomen was negative. On the following day she herself drew my attention to a swelling in Scarpa's triangle which had not been exposed during the previous examinations. The diagnosis of strangulated femoral hernia was apparent.

CASE 2: Sciatica for which a patient had been treated for weeks was caused by a small spindle-cell sarcoma press-

ing on the nerve. It caused his death four years later by metastases in the brain.

CASE 3: Lumbago after having been treated by a number of physicians was found, after several negative x-ray investigations, to be due to an invasion of the vertebra by carcinoma, the primary focus of which was the prostate.

CASE 4: A young physician just recovering from a long exhausting attack of inflammatory rheumatism, pericarditis and endocarditis complained of pain in the right groin; after a few days caries of a lumbar vertebra was found to be the cause of his pain.

Therefore search carefully for a focus of pathology before assuming that the pain is a functional disturbance.

In the first place, in the physician or surgeon no quality takes rank with imperturbability, and I propose for a few minutes to direct your attention to this essential bodily virtue. Perhaps I may be able to give those of you, in whom it has not developed during the critical scenes of the past month, a hint or two of its importance, possibly a suggestion for its attainment. Imperturbability means coolness and presence of mind under all circumstances, calmness amid storm, clearness of judgment in movements of grave peril, immobility, impassiveness, or, to use an old and expressive word, *phlegm*. It is the quality which is most appreciated by the laity, though often misunderstood by them; and the physician who has the misfortune to be without it, who betrays indecision and worry, and who shows that he is flustered and flurried in ordinary emergencies, loses rapidly the confidence of his patients.

In full development, as we see it in some of our older colleagues, it has the nature of a divine gift, a blessing to the possessor, a comfort to all who come in contact with him. You should know it well, for there have been before you for years several striking illustrations, whose example has, I trust, made a deep impression. As imperturbability is largely a bodily endowment, I regret to say that there are those amongst you, who, owing to congenital defects, may never be able to acquire it. Education, however, will do much; and with practice and experience the majority of you may expect to attain to a fair measure. The first essential is to have your nerves well in hand. Even under the most serious circumstances, the physician or surgeon who allows "his outward action to demonstrate the native act and figure of his heart in complement extern," who shows in his face the slightest alteration, expressive of anxiety or fear, has not his medullary centers under the highest control, and is liable to disaster at any moment. I have spoken of this to you on many occasions, and have urged you to educate your nerve centers so that not the slightest dilator or contractor influence shall pass to the vessels of your face under any professional trial. Far be

it from me to urge you, ere Time has carved with his hours those fair brows, to quench on all occasions the blushes of ingenuous shame, but in dealing with your patients emergencies demanding these should certainly not arise, and at other times an inscrutable face may prove a fortune. In a true and perfect form, imperturbability is indissolubly associated with wide experience and an intimate knowledge of the varied aspects of disease. With such advantages he is so equipped that no eventuality can disturb the mental equilibrium of the physician; the possibilities are always manifest, and the course of action clear. From its very nature this precious quality is liable to be misinterpreted, and the general accusation of hardness, so often brought against the profession, has here its foundation. Now a certain measure of insensibility is not only an advantage, but a positive necessity in the exercise of a calm judgment, and in carrying out delicate operations. Keen sensibility is doubtless a virtue of high order, when it does not interfere with steadiness of hand or coolness of nerve; but for the practitioner in his working-day world, a callousness which thinks only of the good to be effected, and goes ahead regardless of smaller considerations, is the preferable quality.—From *Aequanimitas*, William Osler.

It has been said that in prosperity our equanimity is chiefly exercised in enabling us to bear with composure the misfortunes of our neighbors. Now, while nothing disturbs our mental placidity more sadly than straightened means, and the lack of those things after which the Gentiles seek, I would warn you against the trials of the day soon to come to some of you—the day of large and successful practice. Engrossed late and soon in professional cares, getting and spending, you may so lay waste your powers that you may find, too late, with hearts given away, that there is no place in your habit-stricken souls for those gentler influences which make life worth living.—From *Aequanimitas*, William Osler.

VOL. VII MARCH, 1924 No. 3

EDITORIAL

The Mellon Tax Plan

The paramount issue before Congress and the American people today is the so-called Mellon plan of tax reduction. The need for increased taxation to meet the various governmental activities incident to the World War necessitated special tax measures. Authorities differ as to the advisability of the particular methods adopted. It has become more and more apparent that the distinction made between taxable and tax-exempt securities has greatly curtailed business enterprise and has affected business activities in general. The medical profession has been affected for the greater part indirectly by the situation.

In an article which appeared in the A. M. A. Journal for January 26, 1924, entitled "Why the medical profession should be relieved from present tax burdens," a concise statement appeared of the

arguments why certain changes in federal tax laws should be made.

Under the Harrison Narcotic Act, as amended by the Revenue Act of 1918, the narcotic license fee for physicians was increased from one to three dollars. Inasmuch as the income from this act from all sources largely exceeded the cost of the enforcement of the act, the increased fee is essentially a special tax discriminating against the profession. While the sum is rather insignificant to the individual physician, the total sum in Minnesota alone amounts to several thousands of dollars.

According to the present income tax laws, the physician may charge to professional expense certain items incurred in the pursuit of his profession. This includes membership in medical societies and traveling expenses in consultation work. The Commissioner of Internal Revenue has ruled, however, that expenses incident to medical society meetings or post-graduate study are not deductible from the gross income of the physician as not being strictly necessary professional expense. Such a ruling tends to restrict the attendance on medical meetings, discourages self-improvement in the physician and works to the detriment of the public at large.

The new federal tax law contemplates placing a lower tax rate upon earned incomes as distinguished from income from investments. The idea is a new one, but one which seems reasonable and one which would work to the benefit of the profession.

The poll of the nation at present being conducted by the Literary Digest is of interest and shows a predominance of opinion in favor of the Mellon plan. It would seem that those in opposition to the plan must be influenced by a narrow conception of the purpose of any tax. Any tax which discourages the branching out of business or professional activities is pernicious.

Money Matters

The physician has been proverbially a poor financier. The present day physician is much more business-like in the management of his financial affairs than formerly, but there is room for improvement.

The practice of medicine is a profession and the evaluation of medical services in money is often a most difficult matter. In each locality, however,

fees for professional services are pretty well standardized while each physician is forced to modify his charges according to the patient's ability to pay. This does not mean that a physician should charge what the traffic will bear.

Efforts have been made by county societies from time to time to draw up fee schedules for the particular locality concerned. As a rule such schedules have been intended for the general practitioner and have affected only a small percentage of the membership. Fee schedules for surgical procedures are difficult to determine for one reason, because preoperative and postoperative care are such variable factors. Any schedule must of necessity allow considerable leeway in either direction, for each physician must use his discretion in charging his patients more or less than the scheduled fee according to the financial status of the patient. A schedule of fees would be of distinct value in workmen's compensation and insurance work as thus the fee rate would be established by the profession and not by insurance companies or the lower courts. After all is said and done, the fee schedule has not proved practical.

The distinction between free and pay patients should be more clearly drawn. Most physicians give a certain amount of their time and are glad to do so in connection with free hospital or clinic activities. The experience obtained in such work is generally considered ample compensation. This is fortunate, for the profession gets little credit from anyone for such service rendered. On the other hand, the profession has the right to demand that patients able to pay medical fees be not treated at free clinics, whether supported by state, county, city, or private society. Just because a clinic or hospital is supported by taxes is no reason why every one is entitled to free medical attention. If it is argued that every taxpayer is entitled to free care at a city hospital, for instance, the argument is equally sound that the medical staff is entitled to pay for services rendered. The medical profession donates its services to municipal and certain state hospitals and clinics, but the class of patients treated by such institutions should and can be controlled by the local medical society. The importance of competent social service work in connection with free clinics is apparent.

The conscientious physician is only too ready to offer a patient in financial straits the privilege of going to a free institution. Thus the free institu-

tion performs a service to patient and physician alike.

In recent years the state has undertaken the treatment of tuberculous and venereal disease, with the idea that the treatment of these transmissible diseases needs state assistance in order to prevent infection. The time element in the treatment of tuberculosis makes the financial drain on the afflicted individual particularly burdensome, and practically the profession has not suffered from the assumption by the state of the treatment of these individuals. The insistence on the treatment of venereal patients necessitates in a few instances the treatment of individuals well able to treat with private physicians. The dissemination of knowledge incident to state activities along these lines, as a matter of fact, has increased private examinations.

In certain localities the physicians have joined the local commercial credit bureaus and are thus in a position to know the deadbeats in a community. The physicians in the larger cities are at a distinct disadvantage in this respect. Business men in any community recognize the value and importance of credit bureaus and listings. It is high time that each county society established such a bureau. On the other hand, we are not in favor of medical societies acting as collection agencies.

The time has long since gone by when the physician sent out his statements every six months or kept no books at all. Statements should be sent out promptly on the first of each month. Business methods in the practice of medicine are no reflection on the profession and uniformity in such matters would do much to correct the impression generally prevalent that doctors' bills may be left to the last.

MISCELLANEOUS

ELECTRIC LIGHT AND POWER BONDS—A GOOD EXAMPLE OF THE THINGS THAT MAKE AN INVESTMENT WORTH BUYING

By SAMUEL O. RICE
Educational Director,

Investment Bankers Association of America

This article comes right down to specific classes of bonds and endeavors to convey essentials in what investments to buy and why to buy them. Electric light and power bonds of sound, well-managed companies are among the safest and most desirable investments. The reason they are so

is because the demand for electricity is greater than the electrical industry can supply, although electrical companies are annually putting more than a billion dollars a year into extensions and improvements of their plants and transmission lines.

The foregoing is only one of many sound reasons why the electrical field is so desirable for investors. There are many others. But don't understand me to say that all electric light and power bonds are good buys. That is not true of any class of investments, commodities or property. The investor should have dependable information that the bonds he buys are those of sound, well-managed companies. He should know that the general field or class he contemplates investing in is sound. Electricity can sell more of its product that it can produce and the demand is constantly increasing. There is no substitute for electricity. But all electrical companies are not well-managed or conditions in some locality may make it difficult for a company to succeed although it be engaged in one of the most prosperous lines of business in the world.

Sales of electricity by central stations in the United States will run close to \$1,300,000,000 this year. The very reliable *Electrical World* makes that estimate. The total sales of electricity for the first six months this year were \$649,300,000, which was 19.5 per cent more than the \$542,000,000 received in the first six months of 1922. In the first six months this year electrical companies issued in excess of \$600,000,000 in stock, bonds and notes to obtain capital for extensions and betterments of generating plants and transmission lines. As I said, electrical companies are putting more than a billion dollars a year into extensions and improvements in an effort to keep up with the demand for more and more electricity.

Where is all this demand for electricity coming from? Is it sound? Will it last? Those are pertinent questions. Let us consider the three great markets that buy electricity. These three are electric lighting, electric railways, and electricity for power uses in industry, in mills and factories. The greatest demand for electricity is from the industries, although many persons erroneously believe that the greatest market for electricity is for lighting homes and streets.

There were 24,351,676 homes in the United States when the 1920 census was taken. Of these only about 8¼ million homes are lighted by electricity. That leaves a great number of homes yet to be lighted by electricity. Of these, a large number are included in about 7 million farm homes, but quite a few millions of homes without electricity are city and town homes and daily many of them are becoming electricity users. Homes having electric lights generally have greatly increased their consumption of electricity by more artistic and better lighting. Bridge lamps and several colorful table lamps are common in almost every living room and parlor where a few years ago one single electric globe sufficed. The number of electric lights has been increased in every room in every modern home, be it bungalow or mansion. Added to this increase in illumination is the use of electricity for cooking, for operating washing machines and other home appliances and for ironing.

Electricity was first most largely used for lighting. Then electric railways developed and became the greater market for current. Today, however, factories and mills that use current for power are the greatest market for electricity. It is a tremendous new development that the public knows little of. I know one industrial plant whose electricity bill runs close to \$35,000 a month.

But there is still another development in the electrical industry that every investor and prospective investor should appreciate. It is "super-power," the interconnection of different electricity companies so that the greatest economy and efficiency in producing and distributing current can be brought about. A few years ago this interconnection was impracticable because the industry did not know how to handle high voltages economically. Current is most cheaply transported on high voltage lines. Improvements, largely in insulation, have made it practicable to transport high voltages economically considerably more than a hundred miles and thus greatly increase the efficiency of generating plants. A few years ago, no matter how much current it could produce, a plant was limited in its "output" because it could not transport electricity a long distance. Now all that has been worked out and interconnection between plants hooks up many states.

It is impossible to portray in this short space all the great picture of "super-power" and interconnection. One little advantage of this development will indicate its great importance and usefulness. Water power electric plants usually have two extremes in production of current. Low water and flood may both cut down the current producing by the hydro-electric plant. In such a situation a hydro-electric plant might not be able to serve all its customers. In many cases interconnection solves that difficulty. The current simply is drawn from some steam power electric plant perhaps a hundred or more miles away. Likewise, when the water-power plant is operating at full capacity the distant steam plants can cut down on the use of coal by drawing current through their interconnection with the water-power plant.

I mention only a few salient points to indicate the sound field of the electrical industry. Any business that has as large a usefulness and demand cannot but be fundamentally sound. Would I advise physicians to buy electric light and power bonds? I wouldn't advise anybody to buy anything. Every man's investment requirements are different from those of every other man or woman. A person's income, obligations, dependents and many other conditions should be carefully considered and his investments be made to fit that situation. I write this only to suggest that anyone with something to invest consider the electrical industry. There are other utility bonds and industrial bonds just as safe and desirable as the best electric light and power bonds. All should be considered and the investor should keep their characteristics in mind so that he may diversify his investments, not put them all in one enterprise. My suggestion is not to buy electrical industry bonds, or any bonds or stocks without first consulting an honest, established dealer in securities. It is the greatest essential in making sound investments.

OBITUARY

DR. LUTHER EMMETT HOLT

Dr. L. Emmett Holt, who died in Peking, China, on January 14, 1924, will perhaps be longest remembered as the author of a book, "The Care and Feeding of Children," which, through twelve editions, has been for twenty-five years an authority in the homes, not only of the United States, but of South America and Europe, and in China and Japan, where it has been invaluable in medical missionary work.

Recognized as a physician of the highest rank and standards, his influence with his profession was invaluable in removing doubts concerning the value of popularizing health education. After the Child Health Organization program had grown up under his stimulating leadership, he enthusiastically joined with several directors of the American Child Hygiene Association, of which he had formerly been president, in bringing about an actual consolidation of these two great organizations in the American Child Health Association, of which Secretary Herbert Hoover is the president, and of which Dr. Holt served as first vice president from its beginning.

Dr. Holt was born on March 4, 1855, at Webster, N. Y., was graduated from the University of Rochester in 1875, took his master's degree three years later, and, in 1880, was graduated from the College of Physicians and Surgeons of Columbia University. Later, when his work had brought him fame, he received the honorary degrees of LL.D. from Rochester, and Sc.D. from Columbia and Brown Universities.

Dr. Holt's activities covered a wide field, but were devoted to a single interest. From 1890 to 1901, he was Professor of the Diseases of Children at New York Polyclinic, and from 1901, Clinical Professor in the Diseases of Children at the College of Physicians and Surgeons. At the time of his death, he was physician-in-chief at the Babies' Hospital, member of the Board of Directors and Secretary for the Rockefeller Institute for Medical Research, and Trustee of the University of Rochester. He was a member of the Association of American Physicians, retiring president of the American Pediatric Society, and a trustee of the New York Academy of Medicine.

He conducted important research on infant metabolism and was the author of a number of pediatric papers. His book on "The Diseases of Infancy and Childhood" has been the standard textbook in pediatrics in the medical schools of the country.

Though nearly seventy years old, he went to China in August, 1923, as special lecturer at the Union Medical College in Peking, an institution maintained by the Rockefeller Foundation. His death is a loss, not only to the nation, but to the world, whose children he made it his mission to save and serve.

DR. O. S. CHAPMAN

Dr. Ozias S. Chapman, one of the oldest physicians in Minneapolis, died Tuesday, February 5, 1924, at his home, at the age of 84 years.

During the Civil war Dr. Chapman had charge of a large military hospital at Cincinnati. He was a member of the George Rawlins post of the G. A. R., a member of the Hennepin County Medical Society, the Minnesota Medical Association and the American Medical Association, and was active in the work of the Congregational church.

Dr. Chapman was born in Niagara Falls, New York, on March 11, 1839. He received his primary and high school education at Lockport and came to the West when he was 18 years old. For a time he studied at the University of Minnesota, but his education was interrupted for some time by the Civil war. He was graduated by the Miami Medical college at Cincinnati and in 1867 moved to Kansas City, where he remained until 1873. In that year, because of poor health, he moved to Massachusetts, where he continued in practice until 1879. Later he went abroad and upon his return settled in Minneapolis in 1881.

Surviving are his widow, Mrs. Adelaide C. Hayward Chapman, two brothers, Edmund G. Chapman of Duluth, and Arthur A. Chapman of Pueblo, Colo.; two sisters, Mrs. M. L. C. Dunn and Miss Angeline Chapman, Minneapolis, and a niece, Miss Letah Chapman.

DR. H. B. CROMMETT

Dr. H. B. Crommett died February 6, 1924, at his home, Amery, Wis. Dr. Crommett is a graduate of the Medical College, University of Minnesota, in the year 1896. He first located at Montevideo, Minn., and in 1900 removed to Amery, Wis., where he had since practiced his profession.

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

STATE MEDICAL MEETING

The annual meeting of the State Medical Association will take place October 8-10, 1924, at St. Cloud. The program committee consisting of the chairman and secretary of the Surgical Section, Dr. A. C. Strachauer, Minneapolis, and Dr. V. C. Hunt, Rochester, the chairman and secretary of the Medical Section, Dr. E. L. Tuohy, Duluth, and Dr. C. N. Hensel, St. Paul, and the secretary of the Association, had its first meeting February 13. The various problems in the arrangement of a comprehensive program were discussed. It was decided to arrange a program similar to previous state medical programs, affording an opportunity for members of the Association to present subjects in which they are particularly interested and which will be of interest to the members. Members are invited to send in to the secretary of the Association, 402 Guardian Life Bldg., St. Paul, the titles of subjects they desire to present. It will of course be incumbent on the committee to pick and choose in order to make up a well balanced program. Titles must be in the hands of the secretary by April 15. Prompt notification of acceptance or rejection will be made about May 15.

HENNEPIN COUNTY MEDICAL SOCIETY

Under the auspices of the Alpha Xi chapter of the Phi Delta Epsilon fraternity of the University of Minnesota, Dr. Morris Fishbein, a member, and associate editor of the Journal of the American Medical Association and of Hygeia, will speak at the regular Wednesday noon meeting of the Hennepin County Medical Society, March 19, 1924, in the library rooms in the Donaldson Bldg., on the subject of "Preparation of a Medical Manuscript." In the evening of the same day, and at the same place, Dr. Fishbein has consented to speak more formally and at greater length on the subject of "Medicine and the Press." This topic will be discussed by members of the medical and newspaper press. These meetings will be open to the medical profession in general.

THE MINNEAPOLIS SURGICAL SOCIETY

The regular monthly meeting of the Minneapolis Surgical Society will be held Thursday, March 6, 1924, at the Minneapolis General Hospital. Operative clinics will be held by Dr. J. F. Corbett, Dr. E. C. Robitshek, Dr. Olson, Dr. Lynch, Dr. E. Moren, Dr. S. R. Maxeiner, and Dr. A. A. Zierold. A luncheon will be served at the hospital at 12:30 P. M. followed by a pathological conference.

A dinner will be served at the General Hospital at 6:30 P. M. followed by the presentation of cases and a paper by Dr. Angus Cameron, of the University of Minnesota, on "Luetic Bursitis."

SOUTHERN MINNESOTA MEDICAL ASSOCIATION

The annual meeting of the Southern Minnesota Medical Association will be held at Mankato, Minn., May 19, 1924. Members having papers they wish to present are asked to send the titles as soon as possible to the chairman of the program committee, Dr. H. W. Meyerding, Rochester, Minn. All communications regarding the program are also to be sent to Dr. Meyerding.

OF GENERAL INTEREST

Dr. W. C. Portman, of Jackson, is spending the winter on the west coast.

A son was born to Dr. and Mrs. D. N. Berkman of Rochester, January 29, 1924.

Dr. B. L. Laver, of Guy's Hospital, London, is spending several months at the Mayo Clinic.

Dr. and Mrs. C. A. Rathbun of St. Cloud are receiving congratulations on the birth of a son.

Dr. Otto Aagaard of Dr. Rovsing's clinic in Copenhagen is spending a month in Rochester.

Dr. C. H. Patterson, Barnesville, has been elected chief of staff of St. Ansagar's Hospital in Moorhead.

Dr. John A. Watson of Minneapolis is now medical and surgical counsellor at Mudbaden Sanatorium, Jordan.

Dr. Louis Faust, a Fellow in the Mayo Foundation, was married to Miss Elsie Eaton of Rochester on January 15.

Dr. C. J. Hutchinson, formerly of Rochester, has announced his connection with the Kenosha Clinic, Kenosha, Wisconsin.

Dr. H. F. Helmholtz was elected President of the Northwest Pediatric Society at the meeting held in St. Paul on January 31.

Dr. and Mrs. D. E. Seashore of Duluth have just returned from Miami, Florida, where they have been for the past month.

Dr. and Mrs. J. A. Freeborn of Fergus Falls are now in New York City, where Dr. Freeborn is taking a post-graduate course.

Dr. A. W. Adson delivered the Joyce Memorial Lecture in Portland, Oregon, on February 14. His subject was "Trifacial Neuralgia."

Mr. Perrin C. Galpin, Secretary of the Commission for the Relief of Belgium, visited the Mayo Foundation the latter part of January.

Dr. and Mrs. Arthur Steen of Cottage Grove, left the early part of February for Los Angeles, where they will spend the remainder of the winter.

Dr. A. E. Baldwin, who recently completed his internship at Phalen Hospital, St. Paul, is now engaged in the practice of medicine at Brownsdale.

Dr. Thomas O. Young, formerly of the Mayo Clinic, Rochester, has established offices in Duluth for the practice of surgery and surgical diagnosis.

Dr. J. W. Snyder, formerly of Rochester, has announced the opening of offices for the practice of general and thoracic surgery in Indianapolis, Indiana.

Dr. William J. Greenfield, formerly a member of the Mayo Clinic, Rochester, is now engaged in the practice of eye, ear, nose and throat work in Minneapolis.

Dr. Frederick Van Valkenburg, who recently completed his course in medicine, is now associated in practice with his father, Dr. B. F. Van Valkenburg at Long Prairie.

Dr. T. J. Kinsella, formerly a Fellow in the Mayo Foundation, and later connected with the Nicollet Clinic, was married to Miss Sara Monahan at Cedar Rapids on January 28.

Dr. Homer F. Swift, of the Rockefeller Institute for Medical Research, spent February 19 and 20 in Rochester and gave a Mayo Foundation Lecture on "Rheumatic Fever."

Dr. O. H. Ternstrom, formerly of St. James, is now located in Minneapolis for the practice of medicine. Dr. F. L. Bregel succeeds Dr. Ternstrom in his practice at St. James.

Dr. Emanuel Libman, Professor of Clinical Medicine, Columbia University, who visited the Mayo Clinic in January, gave a Mayo Foundation Lecture on "Endocarditis," January 22.

Dr. and Mrs. J. W. Meighen, of Ulen, are in New Orleans, where Dr. Meighen is taking a post-graduate course in the treatment of diseases of the eyes, ears, nose and throat.

Dr. F. G. Kohler of Hector has associated with him in the practice of medicine, Dr. Elton H. Smith of Minneapolis, who recently completed his internship at St. Barnabas Hospital.

Dr. Theodor Bratrud, Warren, is now in Boston, where he is doing post-graduate work. He will also take a course of study in New York before returning to Warren some time in April.

Dr. H. W. Froehlich, Thief River Falls, has been appointed a major in the Medical Officers Reserve Corps of the United States army. Dr. Froehlich has been a captain in the reserve corps for the past five years.

Announcement has recently been made of the appointment of Drs. Reuben Johnson and M. N. Moss of Minneapolis, as temporary assistants in medicine and obstetrics respectively, at the University of Minnesota.

Dr. L. M. Brunet, a practicing physician in Cloquet and Duluth, for the past fifty years, has retired from practice in that vicinity and is now located in Detroit, Michigan, where he will make his home with a daughter.

Announcement has been received of the marriage of Dr. C. E. Anderson, formerly of Minneapolis, now a practitioner at Garretson, S. D., to Miss Gracc P. Blake of Berlin, S. D., which took place at the home of the bride's parents January 15.

Dr. James K. Anderson, who has been in Pittsburgh for the past several months taking post-graduate work, has accepted the medical directorship of the Deerwood Sanatorium, Deerwood, where he entered upon his duties the latter part of January.

Dr. J. W. Andrews has severed his connections with the Mankato Clinic, of which he was one of the original founders, and will spend the winter on his fruit ranch in Florida. Dr. Andrews on his return to Mankato will resume his private practice.

Dr. Ogawa, Dean of the Medical School of the University of Kyoto, and Dr. Toda, of Okayama Medical University, who are making a survey of the principal medical schools of America and Europe, spent February 14 visiting the Mayo Foundation and Clinic.

Dr. B. C. Bernard, formerly a member of the staff of the Deerwood Sanatorium, is now superintendent and medical director of the Oakland Park Sanatorium, Thief River Falls, succeeding Dr. M. George Milan, who is now a staff member of the Warren hospital.

Dr. F. C. Schlutz, Minneapolis, has been appointed chief of the Pediatric Department and Professor of Pediatrics at the University of Minnesota Medical School on a full time basis. He will replace Dr. Rodda, who was appointed temporarily on resignation of Dr. Pirquet, who returned to Vienna.

Dr. and Mrs. W. J. Mayo left the first of February for

New Zealand and Australia. Dr. Mayo will attend the meeting of the Australasian conference of the British Medical Association in New Zealand, and will spend about six weeks visiting the various hospitals and universities in those countries.

Dr. E. Z. Shapiro of Duluth, in company with Dr. Charles Giesen of Superior, left February 6 for Vienna, where he will engage in research work. Dr. Giesen began his research work during the year 1914 but with the advent of the war was forced to return to this country. Both physicians will study at the University of Vienna.

"The Child Health Magazine" is the new name of the official publication of the American Child Health Association, which was formerly published under the name of "Mother and Child." The first issue of the new magazine, which is double the size of the former journal, appeared January 1, 1924. The magazine in its new form has an attractive typographical appearance and is fully illustrated.

Benjamin Franklin spent much time in England from 1757 to 1762 representing the American colonies. While there he placed one hundred pounds in the hands of members of the Society of Friends as a trust, to be invested with accumulations, for not less than one hundred and fifty years. Thereafter at the discretion of the trustees, awards were to be made from time to time for the most valuable contributions to science considered by them, either manuscript or published, on the subject of cures, but particularly in relation to surgery, the nervous system and the part "Mind Treating" has in the recovery and preservation of health. Announcement is now made of the first awards of this fund. *Minor award*, Fusakichi Omori of Tokio, unpublished treatise, "The Rotary Knife in Surgery," five hundred pounds and publication of treatise. *Award*, Charles P. Steinmetz of Schenectady, privately published treatise, "The Nervous System as a Conductor of Electrical Energy," one thousand pounds and republication of treatise. *Major award*, Pierson W. Banning of Los Angeles, published work, "Mental and Spiritual Healing; All Schools and Methods; A Text Book for Physicians and Metaphysicians," two thousand five hundred pounds, scholarship.

NEW AND NON-OFFICIAL REMEDIES

The following articles have been accepted by the Council on Pharmacy and Chemistry:

ABBOTT LABORATORIES:

Potassium Bismuth Tartrate-D. R. L.

Ampules Potassium Bismuth Tartrate with Butyn-D. R. L., 0.1 gm.

Ampules Potassium Bismuth Tartrate with Butyn-D. R. L., 0.2 gm.

BRITT, LOEFFLER AND WEIL:

Loeflund's Malt Soup Stock (Dr. Keller's Formula)

HYNSON, WESTCOTT AND DUNNING:

Flumerin-H. W. and D.

LEDERLE ANTITOXIN LABORATORIES:

Corpus Luteum-Lederle
Corpus Luteum Extract-Lederle
Ovarian Residue-Lederle
1 Per Cent Silver Nitrate Solution-Lederle
Whole Ovary-Lederle

PARKE, DAVIS AND CO.:

Ergot Aseptic
Ampules Ergot Aseptic, 1 c.c.
Scarlet Red Sulphonate-P. D. and Co.
Scarlet Red Emulsion, 4 per cent-P. D. and Co.
Scarlet Red Ointment, 5 per cent-P. D. and Co.
Scarlet Red Ointment, 10 per cent-P. D. and Co.

NEW AND NON-OFFICIAL REMEDIES

Potassium Bismuth Tartrate-D. R. L.—A basic potassium bismuth tartrate containing from 64 to 69 per cent of bismuth. For a discussion of the actions and uses, see Bismuth Preparations in the Treatment of Syphilis (Jour. A. M. A., Aug. 25, 1923, p. 661). Potassium bismuth tartrate-D. R. L. is supplied only in the following forms: Ampules potassium bismuth tartrate with butyn-D. R. L., 0.1 gm. (containing potassium bismuth tartrate-D. R. L., 0.1 gm. suspended in 2 c.c. of a 0.6 per cent solution of butyn in a fixed oil); ampules potassium bismuth tartrate with butyn-D. R. L., 0.2 gm. (containing potassium bismuth tartrate-D. R. L., 0.2 gm. suspended in 2 c.c. of a 0.6 per cent solution of butyn in a fixed oil). The product is administered intramuscularly. The Abbott Laboratories, Chicago.

Scarlet Red Sulphonate.—The sodium salt of azo-benzene-disulphonic-acid-azobetanaphthol. The actions and uses of scarlet red sulphonate are essentially the same as those of scarlet R medicinal Biebrich (see New and Non-official Remedies, 1923, p. 275). It is marketed only in the following forms: Scarlet red emulsion, 4 per cent-P. D. and Co., scarlet red ointment, 5 per cent-P. D. and Co., scarlet red ointment, 10 per cent-P. D. and Co. Parke, Davis and Co. Detroit. (Jour. A. M. A., Jan. 19, 1924, p. 209.)

Ergot Aseptic.—A liquid extract of ergot containing the soluble constituents of the drug. It is standardized biologically so that 1 c.c. represents 2 gm. of ergot. The actions and uses of ergot aseptic are the same as those of ergot. The dose is 1 to 2 c.c. injected intramuscularly. Ergot aseptic is marketed only in 1 c.c. ampules. Parke, Davis and Co., Detroit.

Loeflund's Malt Soup Stock (Dr. Keller's Formula).—A preparation essentially similar to extract of malt, U. S. P., but containing a small amount of potassium carbonate. Loeflund's malt soup stock is designed for use in preparing the malt soup of Dr. Keller. Britt, Loeffler and Weil, New York. (Jour. A. M. A., Jan. 26, 1924, p. 303.)

PROPAGANDA FOR REFORM

Intarvin.—Because of numerous inquiries, the Council on Pharmacy and Chemistry publishes a preliminary report on Intarvin. The product is marketed by the Intarvin Company, Long Island City, N. Y. Dr. Max Kahn has applied for a patent on it. Many statements have been

given the lay press by those interested in the promotion of Intarvin, but as yet no publication has appeared in the medical press, except preliminary reports by Kahn. Intarvin is proposed for use in diabetes or in conditions where acidosis occurs. It is a synthetic fat which, it is claimed, can be assimilated by the diabetic without the production of products that cause acidosis, as is the case with ordinary fats when these are consumed by diabetics. Intarvin is stated to be the glyceryl ester of margaric acid admixed with ten to twelve per cent of liquid petrolatum. While the usefulness of Intarvin is curtailed by the discovery of insulin, it should be valuable in planning a diabetic diet if the claims made for it are substantiated. Intarvin is still in the experimental stage and it is unfortunate that so much newspaper notoriety has been given it. Until acceptable evidence is available for its usefulness, palatability and practicability, judgment of its worth must be suspended. (Jour. A. M. A., Jan. 5, 1924, p. 51.)

Firma-Chloro.—Firma-Chloro is marketed by the Chloro Chemical Corporation. According to the label, it is a mixture of chlorinated lime, tincture of iodine, picric acid, potassium chlorate, sodium bicarbonate and glycerin, but the amounts of the ingredients are not declared. The preparation is claimed to be a powerful chlorinated disinfectant. It is alkaline in reaction, hence the iodine which is claimed to be present would be converted to sodium iodide and sodium iodate. Altogether, the claimed formula is an impossible one: Firma-Chloro is another example of an irrational antiseptic. The favorite method of introducing Firma-Chloro is much like that used for "Oil of Salt" (which the A. M. A. Chemical Laboratory found to be essentially a mixture of linseed oil and essential oils, including turpentine, camphor and sassafras), namely, sending letters to manufacturing plants importuning them to have the product used in the first aid or medical department. (Jour. A. M. A., Jan. 5, 1924, p. 53.)

Chemical Foundation Wins.—During the late war, our government seized many German patents on synthetic drugs. Later the Alien Property Custodian, on executive order of President Wilson, sold 4,700 German chemical patents to the Chemical Foundation, Inc. This corporation agreed in turn to license any American firm that could present evidence of reliability in chemical manufacture to manufacture under these patents. As a result of this action, physicians may today obtain different brands of arsphenamin instead of one proprietary "Salvarsan"—and at competitive prices. The same is true of other useful synthetics. About a year and a half ago, President Harding instructed the Alien Property Custodian to take steps to secure the return of all patents sold to the Chemical Foundation, Inc., on the ground that the price paid was inadequate and the transaction illegal. Suit was instituted by the government against the Chemical Foundation, Inc., for the recovery of the patents. The suit was won by the Chemical Foundation, Inc. In the decision of the court, it was held that the price was adequate, for the reason that many of the patents were non-workable and that, therefore, because of the financial risk and hazard, the value of the patents "was too slight and problematical to warrant the payment by American citizens of a sum even remotely

approximating what they might have been worth to the German owners for their monopolistic purposes." Hence, the bill of complaint filed by the government was set aside. (Jour. A. M. A., Jan. 12, 1924, p. 130.)

Case's Rheumatism Cure.—Some years ago, Jesse A. Case was exploiting "Case's Rheumatic Specific" and an adjunct, a "Liver Tablet." This was a fraudulent mail-order quackery and was finally put out of business by the Post Office Department. Now, Paul Case, son of Jesse A. Case, advertises in newspapers that he has a wonderful rheumatism prescription which he is willing to give free. Those who write receive prescriptions which are strikingly similar to the preparations used by Jesse A. Case. However, the prescription of Paul Case starts out with a "Joker" that was not in the prescription of his father. This is "Powdered Gadoeng (Java)." When sending the prescriptions, Case states that best results are obtained with Genuine Gadoeng—and offers to supply the remedies at a moderate price. Gadoeng is a name for *Dioscorea hirsuta* (a plant related to the obsolete American drug, Wild Yam), which grows in Java and is not found in drug stores. Hence, druggists cannot fill the prescription, and those who want the medicine must get it of Case. (Jour. A. M. A., Jan. 12, 1924, p. 145.)

The Action of Salicylates, Cinchophen, Neocinchophen and Related Products.—The latest (1923) edition of Useful Drugs speaks of the salicylates, cinchophen, neocinchophen and related drugs as "highly efficacious" and "exceptionally efficient" in the management of certain phases of arthritis. The assumption that the drugs exert an etiotropic action by destroying bacterial agencies responsible for the disease has repeatedly been disproved. They do not function as germicides, for example, in rheumatic fever assumed to be caused by micro-organisms. Recently, Hanzlik and Painter compared the antiphlogistic effect of salicylates, cinchophen and neocinchophen in experimental edema of head and neck. They concluded that the so-called antiphlogistic action of these drugs as exemplified in the prompt amelioration of objective signs of inflammation, including the swelling and edema of the joints, is not due to a direct action on the inflammatory process. Experimental edema of the head and neck in animals was not beneficially influenced by previous and simultaneous treatment of the animals with sodium salicylate, cinchophen, or neocinchophen. Negative results with respect to antiphlogistic effects have also been observed in the treatment of other kinds of edema. Consequently, it is concluded that the beneficial effects of these drugs in rheumatic fever appear to be produced neither through etiotropic nor organotropic, but rather through symptomatic action, the benefits being mediated through antipyresis and analgesia. (Jour. A. M. A., Jan. 19, 1924, p. 213.)

Diphtheria Antitoxin for the Infant.—In the presence of diphtheria, no age is a contraindication to the administration of antitoxin. The dose for infants of from 10 to 30 pounds and under two years of age has been given as from 2,000 to 10,000 units. The immunity to diphtheria in young infants seems to depend on antitoxin received from the mother through the placental circulation. This immunity is possessed by more than 90 per cent of the children in

the early weeks of life, but at the end of a year this has been lost by about half of them. Serums are well borne by young children, as they have little sensitiveness to foreign proteins. A suitable immunizing dose of diphtheria antitoxin for an infant would be from 200 to 500 units, and the therapeutic dose from 2,000 to 10,000 units. (Jour. A. M. A., Jan. 19, 1924, p. 228.)

Dermatosis From Fur.—Reports have been published of persons who have suffered severe eruptions and irritations of the skin following the wearing of furs. Investigation has shown that these disturbances are caused by paraphenyldiamin, which is used to dye furs black, and by quinone, an oxidation product of paraphenyldiamin, which gives a brown color. The untoward effects may be prevented largely by extreme care in the finishing and dyeing processes, with special attention to remove all excess dye, and particularly traces of quinone from the fur. (Jour. A. M. A., January 26, 1924, p. 307.)

Spectro-Chrome Therapy.—Colonel Dinshah P. Ghadiali is the exponent of "Spectro-Chrome Therapy" and founder of the "Spectro-Chrome Institute." According to a "life sketch" sent out by him, he was born in India, attended a primary school when he was 2½ years old, was in high school when he was eight years old and at the age of 11 acted as assistant to a professor of mathematics and science at Wilson College, Bombay. Since then he claims to have had a remarkable and varied career. "Spectro-Chrome Therapy," we are told, is "The Latest Revelation in the Healing Art." It consists in "the restoration of the healing Radio-Active and Radio-Emanative Equilibrium by Attuned Color Waves." Here is the thesis developed and commercialized by Ghadiali: Every element exhibits a preponderance of one or more of the seven prismatic colors; 97 per cent of our body is composed of the four elements, oxygen, hydrogen, nitrogen and carbon. The preponderating color waves of these four elements are blue, red, green and yellow, respectively; the human body is responsive to these four "color wave potencies." In health our four colors are properly balanced. When they get out of balance we are diseased; ergo, to cure disease, administer the lacking colors or reduce the colors that have become too brilliant. These cures are to be produced, of course, by means of paraphernalia which Ghadiali supplies. He gives a course in "Spectro-Chrome Therapy." At the end of the course, which seems to last two weeks, a diploma is granted. That this "cult" is taken seriously by some is shown by the published testimonials of cures said to have been wrought. Hopeless and credulous patients are being treated for such serious conditions as syphilitic conjunctivitis, ovaritis, diabetes, neuritis, pulmonary tuberculosis and chronic gonorrhea, with colored light. (Jour. A. M. A., Jan. 26, 1924, p. 321.)

Effect of Bromids on Epilepsy.—The harmful effects of the prolonged administration of bromides aside from the skin and intestinal effects, are gradually increasing dullness, heaviness, torpor, stupidity, with greater self-centering of interests and unintelligence. The size of the dose that is necessary to control the fits is probably an important factor in determining the amount of damage that will be done. (Jour. A. M. A., Jan. 26, 1924, p. 325.)

PROCEEDINGS OF THE MINNESOTA ACADEMY OF MEDICINE

MEETING OF JANUARY 9TH, 1924

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, January 9th, 1924, at 8 p. m. Dr. H. P. Ritchie, Vice President, presided. There were 22 members and 1 visitor present.

Prof. R. E. Scammon was elected to honorary membership in the Academy.

The following members reported cases:

1. DR. C. E. RIGGS (St. Paul): Preliminary remarks. For forty years I have met at different times three grave infections of the central nervous system—epidemic cerebrospinal meningitis, infantile paralysis and encephalitis lethargica. The latter name, given by Economo, is unfortunate because 20 per cent of the cases are not lethargic. These three infections have one thing in common: they occur sporadically. For twenty-five years I was on the staff of the City and County Hospital and every spring I expected to see, and was not disappointed in seeing, sporadic cases of cerebrospinal meningitis. I had a similar experience with infantile paralysis and the same is equally true of epidemic encephalitis.

I wonder how much any of us know of the occurrence of epidemic cerebrospinal meningitis fifty or sixty years ago. I recall hearing an old practitioner tell his experience; he and a confrère were practicing in northwestern Ohio and for three weeks during an epidemic he did not have his clothes off. He bled his patients; his confrère purged his; and about the same number died in each instance.

These three diseases have their periods of epidemic influence and it is during the interim that the sporadic cases occur. I think it is pretty well established that as far as two of these infections are concerned—epidemic cerebrospinal meningitis and infantile paralysis—the microbic agent is known. The disease called Australian X is clinically and histologically similar to that of infantile paralysis, and according to Flexner is "an exalted form of epidemic poliomyelitis," but when it comes to encephalitis lethargica, as to the microbic agent the bacteriologists are still at sea.

The most notable work in this line has perhaps been done by the members of the Sinai Hospital staff. They believe they have produced experimental encephalitis and that the globoid organism that they have observed is the inciting cause. These findings, according to Flexner, have never been confirmed except by Thalheimer of Milwaukee. Levaditi and Harvier, McIntosh and Turnbull, Doerr and an associate, Schnabel, have, they believe, experimentally produced encephalitis. Experiments, however, carried out by Flexner and Amoss for a period of four years "failed constantly to yield an unequivocal result."

Febrile herpes may cause an infection that manifests characteristics very similar to those of experimental encephalitis. Expert bacteriologists postulate an identity

between the two processes. While it would appear that laboratory workers are at variance regarding the etiologic agent that causes epidemic encephalitis and the solution of this problem is not yet an accomplished fact (Flexner), the disease is still with us. Its symptomatology is startlingly protean, exceeding that even of syphilis. Last winter we experienced in the Twin Cities a serious epidemic. This year it appeared much earlier (I observed my first cases in October). It is most atypical and most virulent. In one of my patients it simulated an involuntal melancholia and in another it grafted itself on an essential epilepsy, this patient dying with a temperature of 108 degrees.

This evening I wish to report a case of a disorder of personality, arising in one of my patients, suffering from encephalitis lethargica.

Miss E., 17 years. Mother died of pulmonary hemorrhage; father living and well; three brothers and one sister died in infancy; one brother and one sister living and well. Infantile paralysis at 10 years; recovered in five months. Shortly after she developed Sydenham's chorea. This lasted three months. Seven years ago she had an attack of acute articular rheumatism. Has been nervous at times ever since. At these periods it has been difficult to talk. Had an attack of lethargic encephalitis one year ago last spring; was in bed three weeks; was markedly lethargic; would arouse if spoken to, stay awake 15 minutes or so and again fall asleep. Ten days ago tremor was first noticed in right arm; this extended to the right leg, then to the left arm and leg. When she consulted me she was apathetic, took no interest in things and was unable to concentrate mentally. Last June she developed nervous spells, complained of feeling faint; apparently would drop off to sleep; breathing short and quick. If hands or feet were lifted they would fall back as if lead. No change in color in face. These seizures lasted from 20 minutes to several hours in duration. The attacks varied in frequency from one to three in 24 hours and usually occurred on afternoons. Occasionally the seizures would occur in the early afternoon and continue during the night. She would hold her breath in some spells for two minutes; sometimes she would start talking as soon as the attack came on and might continue doing so for three or more hours until the spell passed off. In her conversation she described in detail journeys she never made (fabrications); again she would imagine that she was at a hospital at the front, where she was assisting the doctors and nursing shell-shocked soldiers. Then again she would think of herself as a missionary and would tell Bible stories; she would also quote passages from the Bible and tell where such passages would be found. Her citations as to the passage and place were correct. During these attacks she would frequently hold her hands to her ears and would cry out in terror, "there is another shell," and tremble all over. Then she would fold her hands in prayer, praying for the soldiers and herself. Frequently she would narrate occurrences that had occurred in her own life and usually her descriptions were accurate. This patient was fond of basket-ball and during some of the attacks she was evidently witnessing a game. She would first tell the names of the players; if her friends won a score she would clap her hands vigorously, talking constantly; if they lost she showed her great disappoint-

ment. At times during the progress of the game she would give utterance to the high school yell. Generally in coming out of an attack she would twitch and shake all over. There was no recollection of what she said or did during an attack with the exception of the last few spells, of which she had a confused memory. At times one or both legs would draw up; the leg flex on the thigh and the thigh flex on the abdomen. Occasionally, the arms and legs and whole body would become rigid. At these times she would hold her breath and the right leg would be extended and rigid.

Physical examination showed aortic and mitral insufficiency, moderate myocardial insufficiency and moderate dilatation to the left. There was a mild residual arthritis of wrist, ankle and knee joints.

The neurological examination was negative. Hemoglobin 88 per cent. Blood pressure 130 systolic, 80 diastolic. Urine negative. Serological findings negative. She experienced marked relief after the first lumbar puncture, the attacks greatly diminishing. After an intraspinal injection of auto serum, they were much increased for a week; then practically ceased.

Clearly, this is a case of encephalitis lethargica, with an associated disorder of personality. For the latter, for the want of a better name, we use the archaic term hysteria. Recently Hunt has called attention to this rather unusual association. Hysteria, neurasthenia, and psychasthenia—the so-called psychoneuroses—are not diseases, only syndromes, clinical ensembles as it were, due to the influence of mental stress, physical illness or both on personality—they tend to disintegrate, to disorder it; in fact, the whole gamut of nervousness or nervous manifestations are just so many expressions of their disruptive effect on its normal integration. The functional nervous diseases of forty years ago and the psychoneuroses of a later evolution are now in the discard. They have been touched by the magic wand of the new psychology and are no more—we now marvel at the immaturity of our former concepts.

In the disorders of personality we now find a scientific, a more satisfactory explanation. The struggle of personality within itself, i.e., the inherited instincts versus our acquired experiences; its struggle with the industrial, the social and the moral order; its inherent initial defects; the disruptive influence of mental stress or grave physical illness, or both combined; these constitute the ordeal through which personality in the making must pass in order to become stabilized and normal and it is while passing through this crucible that all these protean nervous and mental symptoms arise. Goethe truly says:

"Two souls, alas, reside within my breast,
And each from the other rends and tears itself."

2. DR. A. C. STRACHAUER presented two cases:

(a) A case of chronic indurated gastric ulcer present since the age of 8 years, treated by excision and posterior gastroenterostomy.

Norvald N., age 11 years.

Complaint: Epigastric pain, nausea, vomiting, and undernourishment.

History: Patient admitted to the University Hospital on Nov. 14, 1923, complaining of epigastric distress, nausea,

vomiting, and loss of weight and strength. Symptoms had developed suddenly three years ago, and consisted of severe epigastric distress coming on about 2 hours after eating, followed in half to three-quarters of an hour later by nausea and vomiting. Vomiting always gave complete relief. Such symptoms might occur as often as twice daily or be absent for several days. The patient found nothing which would relieve the pain except emptying the stomach. Periods of such attacks occurred intermittently but with increasing frequency. The longest interval of freedom from distress since the onset of his illness was 5 weeks. Gradually he began to lose weight. His appetite became poor; he felt weak and listless, and finally was taken from school. Six months ago the pain began to subside. Vomiting persisted and occurred every two or three days. The parents noticed that food eaten the day previous would often be vomited the next day. He continued to lose weight and strength. He had never vomited blood nor, as far as can be ascertained, passed blood in the stools.

Examination at the time of entrance showed an emaciated, under-developed boy, weighing 43 pounds, with no abnormal physical findings except very carious teeth, moderate cervical adenopathy and epigastric distention, in which peristaltic waves could be plainly seen moving across the abdomen to the right. Abdominal palpation negative.

Fluoroscopy of the stomach showed enormous dilatation, atony and complete retention of the barium meal at the end of 6 hours. Findings were conclusive for pyloric obstruction, but did not differentiate between ulcer or congenital stenosis.

While in the hospital he had no fever. He complained of no pain, but unless aspirated daily he refused his food because of a feeling of distention. Routine aspirations each morning varied from 600 to 1,300 c.c. Retention was not relieved by milk and cream diet with acidity controlled by alkalis. Patient gained three pounds while in the hospital.

Laboratory findings:

Gastric content:

Free acid varied from 14 to 35 points.

Combined varied from 37 to 56 points.

Urine—normal.

Stools showed no occult blood.

Hemoglobin, 90 per cent.

Leucocyte count, 10,700.

Polymorph., 79 per cent.

Lymphocytes, 12 per cent.

Wassermann negative.

Von Pirquet negative.

Pre-operative diagnosis:

1. Ulcer.

2. Congenital pyloric stenosis.

Treatment: Ether anesthesia. The abdomen was opened by a right rectus incision, disclosing the stellate scar of a gastric ulcer, the size of a dime, on the anterior wall of the stomach, three-quarters of an inch from the pylorus. On palpation a crater could be felt which readily admitted the tip of the little finger. The stomach wall, over an area the size of a quarter, was markedly thickened.

The ulcer was excised, being one centimeter in thickness, and because of almost complete obstruction at the pylorus a posterior gastroenterostomy was performed.

Pathologist's report: Gross specimen consisted of an excised area of stomach wall measuring $2\frac{1}{2} \times 2\frac{1}{2} \times 1$ cm. in thickness. It showed an induration of stomach wall consisting of firm, fibrous connective tissue. The mucosa showed a definite crater-shaped ulcer measuring 5×7 mm.

Microscopic report: Section of the ulcer showing the thickened stomach wall to be made up of dense fibrous connective tissue with very small blood vessels. This tissue contained a few lymphocytes. The mucosal surface showed a break in continuity corresponding to the area of ulceration described in the gross. **Diagnosis:** Gastric ulcer. (John F. Noble, M.D.)

Subsequent history: Patient made an uneventful recovery and was sitting up on the tenth day after operation.

(b) A case of hydronephrosis in infancy.

Elmer D., age 16 months. Complaint: Abdominal tumor and dyspnea.

History: The patient, a well-developed, well-nourished male infant, was admitted to the University Hospital on December 4, 1923. He weighed 26 pounds, and, except for the abdominal swelling and dyspnea, was apparently in excellent health. Delivery was normal; he was breast-fed for four months. Teeth erupted at normal intervals, and he began to walk at one year. The abdomen was unusually large at birth, and it gradually increased in size. At one year, when he began to walk, dyspnea was noticed. At the same time the swelling became more prominent on the left side and for the first time a soft, fluctuant mass was made out. This became uniformly larger, until at the time of his entrance to the hospital it occupied almost the entire left side of the abdomen. It was never painful. There were no abnormal urinary symptoms.

Examination: A large, soft mass occupied the entire left side of the abdomen from the costal margin to the brim of the pelvis. It imparted a definite fluid wave and moved toward the midline when the abdominal muscles were used. Circumference of the abdomen at the umbilicus was 24 inches, and the same at a level 2 inches higher. A cystic, elastic tumor mass could be felt by rectal palpation. Examination otherwise negative.

X-ray examination: Fluoroscopic examination of the colon showed the splenic flexure and descending portion to be markedly displaced to the right, toward the midline.

Laboratory findings:

Urine normal.

Hemoglobin 70 per cent; red cells 3,640,000; leucocyte count 7,200.

Wassermann negative.

Clinical diagnosis:

1. Congenital hydronephrosis.
2. Mesenteric cyst.

(Because of the patient's age and sex it was not deemed advisable to submit him to cystoscopy and pyelograms. Cystoscopic examination in girl infants is easily performed, but boy infants are liable to traumatization and are to be cystoscoped only under the greatest urgency.)

Treatment: Ether anesthesia. Left rectus incision. The descending colon was mobilized, and an enormous hydronephrotic kidney removed by the transperitoneal route.

Pathologist's report: The specimen consisted of a large hydronephrotic kidney. The entire specimen measured $17 \times 13 \times 11$ cm. The kidney was flattened and thin to form part of the wall of the dilated pelvis and was 16×9 cm. The ureteral pelvic juncture was located at the medial border of the mass and slightly anterior. There was a definite constriction at this point. The dilated pelvis was vascular and the renal vessels entered at the medial border and ran adherent to the wall of the sac to reach the kidney.

Subsequent history: The patient made an uneventful recovery and was discharged from the hospital 16 days after operation. At the time of his discharge the abdomen measured 21 inches in circumference at the level of the umbilicus.

Comment: Congenital hydronephrosis is still rare enough to be of interest when found. A review of the literature discloses 120 reported cases. Approximately three-fourths of the cases are discovered soon after birth, and as time passes the cases which are encountered are less likely to be of true congenital origin.

Most of the reported cases have been unilateral. Stricture of the ureter has been a common cause. The locations of the strictures are at three principal sites: the ureteral pelvic juncture, the level of the brim of the pelvis, and at the ureteral vesical orifice. Twenty to forty per cent of strictures, varying with the series reported, are at the ureteral pelvic juncture and the remainder are at the lower end of the ureter, most commonly at the ureteral vesical orifice.

The following pathological findings have been reported:

1. The presence of fetal folds persisting to form valves or actual constrictures of the ureter.
2. Anomalous vessels causing kinking of the ureter to produce obstruction.
3. Intrauterine inflammatory reactions causing fibrous strictures.
4. Failure of development of all or part of the ureter. (Engelisch has reported 8 cases in which one or both of the ureters are entirely absent.)
5. Anomalous positions of the ureter entering the vagina, uterus or bowel.

There have been a few cases of probable congenital origin in which hydronephrosis and hydroureter have been found without constriction at any point. The etiology of such conditions has been explained by

1. Disturbance of nervous mechanism in which there is a spasmodic contraction of the internal vesical sphincter occurring coincidentally with powerful contraction of the bladder and resulting in back pressure in the ureter and pelvis of the kidney.
2. Inflammatory reaction with erosion of the ureteral vesical orifice destroying the valve action and allowing back pressure from the bladder.
3. A congenital failure of the development of ureteral musculature.

Congenital hydronephrosis must be differentiated most

commonly from mesenteric cyst, ovarian cyst, enlarged spleen, pancreatic cyst and megacolon.

Symptoms consist of abdominal swelling in which a definite mass can usually be made out. Frequency, painful micturition or retention are occasionally found, and in such cases the stricture causing the hydronephrosis is usually at the ureteral vesical juncture. Bottomley reports 17 cases in which a fibrous constricted ureteral vesical orifice projected several mm. into the bladder. All of these cases show some bladder symptoms.

Where cystoscopy, ureteral catheterization and pyelograms are feasible, as in female infants, a positive diagnosis can usually be made.

The transperitoneal route has been the favored method of approach.

In cases of bilateral hydronephrosis, some form of plastic operation must be attempted, but the prognosis in such cases is very poor.

DISCUSSION

DR. A. SCHWYZER: In connection with the case of congenital hydronephrosis, I thought of a case that was very interesting in the obstetric service which I saw when I was assistant in the University Hospital in Zurich. When I was called in to see the case the second assistant had pulled out the arm of the child when he tried to make a version, and he had torn the arm and shoulder-blade clear off. The arm was edematous. I told him right away it was an anomaly and would never have lived. In examining, you felt a soft ballooned mass. With the finger-nail I ripped an opening and relieved a lot of fluid in that way. Then a second sac presented inside of the first one and was emptied in a similar way. This was the bladder. Every part of the child was edematous. This case was due to impermeability in the urethra of the child.

DR. JUDD (Rochester): These are certainly two very interesting cases. I had one case last year of an ulcer on the lesser curvature of the stomach. The patient was a boy 13 years old with a history of 2 or 3 years. It had not produced quite as marked symptoms as this one, although the ulcer was considerably larger than this one. I had the boy on Sippy treatment for two or three months and finally did just as Dr. Strachauer did. I think that is the youngest case we have seen of ulcer of the stomach.

I had a case of congenital hydronephrosis, a child 5 or 6 years old. We have laid so much stress in these cases on constriction of the ureter, but it seems to me that with the picture of this amount of destruction in the kidney tissue there must be some disease in the kidney itself. The kidney substance was pretty well destroyed, yet there was no evidence of obstruction. It seems to me we have not yet gotten at the etiology of hydronephrosis.

3. DR. LITZENBERG showed x-ray pictures of a hairpin which had been introduced into the uterus by the patient and which was removed by vaginal hysterotomy.

4. DR. JUDD (Rochester) reported two cases:

(a) Cyst of the Liver. 412606. M. A. B., male, 4 years of age.

History: The child was brought to the clinic Dec. 11, 1922. He had always been perfectly well until two weeks

previously, since which time he had frequently cried out in his sleep and complained of pain in his stomach. Never a hearty eater, but had never previously complained of any discomfort. No fever or jaundice. No known injuries of any kind.

Examination: Well-developed but rather thin, sallow boy. Submerged septic tonsils. Cervical glands enlarged. Reflexes exaggerated. Palpable mass 8x8.5 cm. in diameter in the epigastrium, movable in all directions. Lambia intestinalis and trichonemads present in stools. X-rays of the gastrointestinal tract negative. Hemoglobin 68 per cent; white cells 16,000; red cells 4,200,000. Urinalysis showed a specific gravity of 1045 and the presence of a slight amount of albumin. Blood Wassermann negative.

Operated Dec. 18, 1922. Tumor about the size of a small grapefruit beginning just beyond the suspensory ligament and involving the left lobe of the liver. Liver incised and cystic mass removed without rupturing it. Individual vessels tied and liver carefully sutured together. The tumor mass proved to be a multilocular simple cyst weighing 260 gms. Convalescence uneventful and patient able to leave the hospital the 13th day and was dismissed from our care 4 days later.

Examined Jan. 5, 1924: Patient had been crying out in his sleep during the past two or three weeks (period of holiday celebrations). When thoroughly awakened, the child did not complain of pain. Hemoglobin 72 per cent; white cells 12,000; red cells 4,650,000. No demonstrable abdominal pathology.

Discussion: This particular case is interesting because of the rarity of the condition and because it shows that a rather extensive operation on the liver can be carried out in a young child.

An accurate diagnosis of the condition could hardly be possible, as there were no indicative symptoms, simply the presence of a tumor. In most instances, the simple cysts of the liver have been multiple and have been associated with multiple cysts in the kidneys. Usually the cysts in the kidneys are extensive and their interference with the renal function may be the only complaint these patients make; there may be no palpable cysts in the liver. In this reported case, the liver was carefully examined and no other cysts could be found. The patient was examined recently, more than a year since his operation, and from all the evidence we could obtain, he is free from cysts in the liver or kidneys, and is well.

(b) Pancreatic Cyst. 392950. A. K., female, single, 54 years of age.

History: The patient came to the clinic May 30, 1922, because of the discovery of a tumor in the epigastrium two weeks previously. No pain or other symptoms from it. Had been constipated for many years. Five years previously she had had a sterile pleural effusion necessitating two drainage operations; in April, 1922, she had had a right-sided pleurisy confining her to the hospital for 10 days. For three or four years she had had marked intolerance of greasy foods and sauces, but no colic or jaundice. No weight loss.

Examination: Negative with the exception of a palpable mass in the epigastrium the size of an orange, which

moved on respiration. Low-lying but normal right kidney. Thickened pleura.

Operated June 13, 1922. Cyst of the pancreas near the head on the upper border with attachment about 3 inches in length, extending more on the posterior than on the anterior surface of the organ. The mass lay in the lesser peritoneal cavity just above the stomach and under the left lobe of the liver. A left rectus incision was made and the cyst enucleated by careful dissection without rupturing it. The pancreatic tissues were clamped superficially so that the ducts were not injured in any way. The abdomen was closed without drainage.

Discussion: In this instance the cyst was different than any other pancreatic cyst we have ever observed. In all the others, the cyst has been situated in the substance of the pancreas. The pancreatic tissue surrounded the cyst and an attempt to enucleate the cyst would have produced a great amount of bleeding, and rather than resort to excision under these circumstances, it has seemed a better policy to drain the cyst, suturing the wall of the cyst to the parietal peritoneum, thereby establishing drainage over a considerable period of time. These cases have done very well, although drainage in some individuals has persisted for a long time, sometimes many months.

In the case reported, the cyst probably should have been classified as a pseudo-cyst, as it was lying between the lesser curvature of the stomach and the liver and apparently arose from the extreme upper border of the pancreas. The entire cyst could be lifted out of the abdominal cavity and by clamping a few small attachments was removed. After these attachments had been tied off, the abdomen was closed without drainage. In every other respect the tumor was characteristic of a pancreatic cyst.

DR. H. B. SWEETSER read a paper entitled "Observations on Carcinoma of the Colon," with report of two cases.

DISCUSSION

DR. STRACHAUER: Malignancy of the bowel is one of the most satisfactory fields in surgery. Carcinoma of the bowel usually grows slowly and is very late to metastasize. Our operability of cancer of the bowel has been very much higher than has been reported by Dr. Sweetser. In fact, in our experience at the University Hospital, it has been the very rare exception that a tumor of the colon has been non-resectible. As to the types of operation to be performed, the indications for the Mikulicz and other types of resection are quite definitely laid out. All tumors of the right colon, that is the cecum, ascending colon and hepatic flexure, are preferably operated upon by the removal of the terminal ileum, cecum, ascending colon and hepatic flexure, an anastomosis being made between the ileum and transverse colon and the abdomen closed without drainage. The Mikulicz operation is indicated in all tumors of the left colon; that is, the transverse colon, splenic flexure, descending colon and sigmoid.

Primary anastomosis in the left colon is too frequently followed by leakage to warrant its performance. The Mikulicz operation is one of the safest and most satisfactory operations we are called upon to perform. By ade-

quate mobilization of the colon a very wide resection of the bowel and mesentery may be effected.

The account of a recent case operated upon at the University Hospital may be interesting. The patient complained of pain in the lower left abdominal quadrant two hours after meals. On palpation a tumor the size of a man's fist could be palpated in this region. At operation a carcinoma of the cecum, which had become adherent to the mesentery of the sigmoid, with extension of the malignancy into the mesentery of the sigmoid, was disclosed. A resection of the terminal ileum, cecum, ascending colon, and hepatic flexure with its fan-shaped mesentery, was performed and an end-to-side anastomosis made of the ileum to transverse colon. The sigmoid was freely mobilized and 14 inches of the same removed by the Mikulicz procedure.

These operations were done through a lower left rectus incision. When necessary to close the colostomy we have found that the same could be more easily performed by including in the closure a margin of the skin. In addition to this method of closure on the human, colostomy in a number of dogs was similarly closed, and we found, after killing the animals and removing the bowel, that the skin was still living and the hair growing into the lumen of the bowel.

DR. A. SCHWYZER (St. Paul): In regard to the diagnosis, I want to mention two cases we have had within a month. One was not carcinoma, but it was interesting as to the diagnosis; it was similar to that Dr. Sweetser has reported. The physician was not urging the operation, because the symptoms did not appear very urgent, and also on account of the patient's age. He had found that the lady, 68 years old, was suffering besides the constipation from insufficient action of the kidneys and weakness and fainting spells. However, there was a mass to be felt on deep palpation in the region of the upper ascending colon. It is difficult to understand why there was not a complete obstruction. There was at least 3 inches of an ulcerated and tortuous narrow channel through a thick carcinomatous mass larger than a man's fist. When water was poured into the cecum and the specimen held vertically suspended, the water would not run through this channel, but stay in the cecum above. An ileo-colic anastomosis was made after removing the whole mass under local anesthesia with $\frac{1}{4}$ per cent novocain. The patient stood the local anesthetic quite well. She had broad adhesions and we had to remove a large package of glands that reached toward the root of the mesocolon. These glands, if they are soft and round and discrete, are as a rule only inflammatory and they felt inflammatory. Nevertheless, they were removed. The microscope showed they were only inflammatory. Just as Dr. Strachauer has found, I have seen few cases that really were inoperable. Not only when the lesion was in the right half of the colon but in almost every case I have made a direct anastomosis. One must always be careful not to drain near the suture line, and we use linen or silk on the outer side. I have done the Mikulicz operation in very debilitated old people. The upper part above the tumor is usually enormously hypertrophic. In this mentioned case, it was enormously so, and I think that was the reason why the patient did not have complete blocking.

The other case we had two weeks ago today. A woman, about 45 years of age, was brought in with complete obstruction. I have rarely seen an abdomen as tense as that one. The obstruction had lasted only two days. She had had repeated doses of laxatives, and seven enemas, with no results. In examining her vaginally, it was noticed that she had a hard mass at the right side in the Douglas. It seemed that it probably was a carcinoma above the rectum. It was thought best to first do just a small ileostomy through a gridiron incision at McBurney's point. We found absolutely collapsed small intestines. No ballooned loop presented. In feeling over toward the left side we found a very tense elastic mass. On its anterior surface we could feel a spread-out tinea, nearly an inch wide. This proved to be the colon. A midline incision was made and an enormous sigmoid was delivered. There was a twist of 360 degrees on the sigmoid flexure and the hard mass in the pelvis was a sub-serous fibroid of the uterus, which we removed. We put the lower part of the sigmoid on the stretch and then sewed it to the parietal peritoneum for a distance of about four inches.

The postoperative course in both cases was quite smooth.

DR. JUDD (Rochester): There is one thing I would like to state again, to emphasize: the thing that we are constantly confronted with in a patient coming in with obscure abdominal symptoms. We have an x-ray of the colon and find carcinoma. These tumors may develop in an obscure way and grow to be very large before they give any evidence of lesion of the colon. Our experience with resection would be about the same as Dr. Miller at Hopkins. In operating for carcinoma of the right colon it seems to be a pretty radical procedure. You can very easily take out a segment and make an end-to-end or lateral anastomosis. It is safer to take out the coil and then join. I like to do an ileostomy at the same time. I used the Witzel technic; I put a catheter in and put a clamp on it. If there is no distention and the gas is expelled without difficulty, it may never be necessary to release the clamp from the end of the catheter and it may just be left in place until the catheter comes out of its own accord, in about 10 days. On the other hand, if there is distention, nausea, vomiting or paresis, it is well to free the clamp from the catheter and allow the gas and liquid feces to escape. This usually greatly relieves the patient. In the cases in which we have not used the catheter, it is seldom necessary to do a secondary operation for obstruction or paresis, but some patients have been distended a good deal and very sick for a number of days. This can be entirely relieved by the use of the enterostomy.

With carcinoma of the left colon, I think, as Dr. Strachauer says, they do represent a fairly satisfactory class, but they are primarily a big hazard and represent a higher mortality than the other resections. This has led us to do practically all cases in two stages. The patient may get along apparently all right for a week and then develop peritonitis, which it seems to me is explained by the fact that the circulation in the left colon is definitely distributed in segments. In one case the circulation may not seem to be greatly disturbed and the case gets along well, but in another case apparently done just as accurately and giving the same appearance at operation, the circulation

to one of the segments may be poor and the patient die as a result of necrosis in this portion of the intestine. In resections of the left colon, it seems to me the better plan is to do a radical Mikulicz operation if it can be done. With low tumors, it is sometimes very difficult to get the growth out well.

In operating for obstruction, it is better to do a complete ileostomy or a colostomy first, so that at the time of the second operation there will be practically a clean field. The colostomy enables us to wash out the lower segment and the performance of a clean operation.

DR. STRACHAUER: Dr. Judd's description of the blood supply to the colon is an explanation only in part for the failure of the colon to heal in primary anastomosis. We must recall that the colon is only partially covered by peritoneum and is not surrounded by a complete investiture as in the case of the intestine. Successful anastomosis of the bowel is absolutely dependent upon the apposition and adherence of serosa to serosa. This can not be accomplished in the posterior portion of the colon, which lacks the peritoneal covering. This, in addition to the blood supply, is the explanation of the common occurrence of leakage following resection and immediate anastomosis.

DR. SWEETSER (in closing): I just want to add a word. Of course, we understand that resection of the bowel for carcinoma carries with it a certain mortality which cannot be avoided by any method of operation. If, now, the mortality from resection and preliminary colostomy is no greater than that from the Mikulicz or two-stage operation, then, surely, from the standpoint of the patient, the former is the preferable method, as it gives a shorter and less distressing convalescence. That there is little difference in choice as regards mortality in the two methods may be seen by comparing the results in the respective series of Dowd and of Miller. Dowd had one death in 8 cases done by the Mikulicz two-stage method, a mortality rate of 12½ per cent; and Miller reports one death in 13 cases done by resection with preliminary colostomy, a mortality rate of 8 per cent.

DR. F. L. ADAIR read a paper entitled "Placental Infarcts and Their Relation to the Toxemias of Pregnancy," illustrated by several lantern slides.

DISCUSSION

DR. CONDIT: I would like to ask Dr. Adair how much of the mechanical element he can eliminate as an etiological factor in the production of the injury to these placenta he describes in the plates as congestion, hemorrhages and even some of the thrombi. There may be marked damage done to the placenta at delivery from muscular contraction of the uterus alone, and more if delivery of the placenta is prolonged or Credé used in completing the third stage.

DR. LITZENBERG: Young, whom Dr. Adair quoted, and Dr. Adair's paper are two illustrations of two different kinds of minds approaching the subject. Young found so many cases of infarcts in the placenta that he came to the conclusion that it was the cause of the toxemia. I remember saying at a previous discussion of Young's paper in one of our departmental meetings that it seemed to me that one could come to the exact opposite conclusions from Young, using the same data. I think Dr. Adair has suc-

cessfully refuted Dr. Young's contention that infarcts are etiological; and that they are more likely to be an effect from some unknown cause. Dr. Adair spoke of cases of toxemia that had no infarction. I have seen women who had convulsions who had no infarcts in the placenta. However, they occur so frequently in the toxemia of pregnancy that they must have some relation, although it is not a constant relation. Just what the relation is, it is difficult to say. We clinicians are apt to get impressions without very careful analysis. I have the impression that in the cases of pregnancy with a true nephritis infarction is very constant, but I think that it is a wise thing for us to pause and not to be carried away too far even by a man of Young's standing.

One other thing that Dr. Adair concludes that in the light of our present knowledge is quite logical, but which may at some future time be found to be not true. He says some of these cases are not toxemic—one woman was "not definitely toxic, yet not just right." Sometime when we know more we may have a different idea. There may be women who are toxic who do not show the toxemic symptoms as we think of them now. Some of these women may be mildly toxic that have these infarcts.

DR. HAMMOND (St. Paul): When I was in the maternity hospital in Montreal we used to keep pretty close track of the placenta and were particularly interested in infarcts. I think at that time we came to the conclusion that infarcts were almost always seen in cases where nephritis or high blood pressure were present or where there were definite signs of toxemia and we always looked upon the infarct as the result of kidney changes or toxemias. At that time we did not consider them as the cause of the toxemia.

I sent a rather interesting specimen over to the University today. The woman had gone overtime three or four weeks, according to her dates. The child was always more or less inactive. The fetal heart was rather indistinct, but definitely heard up to the time labor began. The woman went into labor; she had had some albumen but no signs of toxemia. At the time she went into labor the fetal heart was heard, but rather indistinct. There was a short normal first stage. At the beginning of the second stage the fetal heart was still more indistinct. In the course of two hours she was delivered. The child was dead. It was a very much under-nourished child, weighing six pounds. It was 44 cm. long, showing that it was overdue. The cause of the death of the child was a large infarct, at the insertion of the cord, which had gone on to cystic change. It shut off about half the circulation. There was no doubt about the cause of the death of the child in that case.

DR. LITZENBERG: I would like to ask Dr. Adair if he found any considerable number of fulminant cases that have no infarcts and also if there were any considerable number of cases of nephritis without infarcts.

DR. ADAIR (in closing): In answer to Dr. Condit's question, I would say that there are, of course, many changes seen in the placenta which cannot possibly occur in the short period of time elapsing between delivery of the child and delivery of the placenta. That a certain amount of congestion might result during the third stage is, I suppose, possible. That we could have congestion of the villi I

imagine is possible and yet I think a good deal of the congestion is on the fetal side, and after the child is delivered it would be rather difficult to explain why it should occur on the fetal side. It might be difficult to explain why this occurred only in localized areas. I really do not believe the retention of the placenta during the third stage to be much of a factor in causing these changes in the placenta.

With reference to Dr. Litzenberg's remarks, I showed some specimens from cases that gave no clinical signs of toxemia. This really is only indirect evidence that infarcts do not cause toxemia. The more conclusive evidence would be a rather marked toxemia without the presence of infarcts in the placenta. If we could demonstrate that, it would be almost conclusive evidence and I believe my specimens do show this. In many placenta you find old white infarcts.

In the fulminant cases of toxemia, infarcts are very common, especially these areas of recent degeneration and hemorrhage.

I think we find white infarcts especially in the more chronic cases, which would lend support to the idea that the white infarcts result from degenerative changes if the placenta remains long enough in the uterus.

In regard to nephritis, the two cases that I showed who had a high blood pressure evidently had previous hypertension with exacerbation during pregnancy. Whether or not there was any other cause is hard to tell. They both had various changes, both old and recent.

I have not seen a case such as that mentioned by Dr. Hammond, where an infarct obstructed the umbilical circulation. Extreme degeneration of the placenta is responsible for the death of the fetus. When a child outgrows the placenta, of course, it dies. This may account for some fetal deaths late in pregnancy. The child's growth continues as long as the normal placental tissue is able to meet its demands. If then the demands are not met, the child may die in utero.

JOHN E. HYNES,
Secretary.

TRANSACTIONS OF THE MINNEAPOLIS SURGICAL SOCIETY

STATED MEETING HELD NOVEMBER 8, 1923, THE PRESIDENT,
J. M. HAYES, IN THE CHAIR

Immediately before the regular meeting, the society presented Dr. A. W. Abbott with a small token of the respect of the profession which he has maintained through his fifty-five years of medical practice.

Dr. Farr made a concise presentation speech, as follows: Mr. Chairman, Members of the Minneapolis Surgical Society and guests:

Were it not for the realization of my almost total lack of ability to meet the requirements which have been imposed upon me by this society, the duty which is mine to perform would be one of the greatest pleasures of my life. I trust that any inadequacy on my part will melt into obscurity in your minds, which I know full well are surcharged with the consciousness that in honoring our es-

teemed confrère, Dr. Amos W. Abbott, we are honoring ourselves a hundred-fold.

Dear Doctor Abbott, we want you to know that we appreciate the fact that for fifty-five years you have been a potent factor in the growth and development of surgery; that you have been a leader in fostering medical progress; that your high medical and social standing have added greatly to the esteem in which our profession is held; that the enviable pinnacle upon which you stand today, after all these years on the firing line—years in which you were often tried but never found wanting—is constructed upon the qualities of honesty, integrity, perseverance and diligence, combined with an inherent modesty, love for your fellow men and the practical application of the Golden Rule. As an example to younger men your influence is undoubtedly the most marked of any with which I am familiar. Time will not permit the recounting of even a small portion of your attainments and yet from my own personal experience some indication of your qualities may be gained.

We all know something of your Civil War record. I have seen you meet adversity, which comes to all of us at times, with stoicism and without complaint. I have called you in council upon cases which I thought difficult only to learn that I needed a little more schooling. Upon each occasion I was instructed in such a manner that my respect and esteem for you increased—while the attitude of my patient towards me grew more respectful in a like manner. I have seen you during recent years remove a tumor, take it into your own laboratory, make frozen sections from it, dispute with a prominent pathologist regarding the diagnosis and win the debate. I well remember when, some years ago, I was seriously injured and taken to the City Hospital that you were the first of my medical friends to call upon me. I have borrowed money so often from you at medical conventions that during recent years your frequent voluntary offers of financial assistance have been the means of saving me great embarrassment.

And now, gentlemen, if close association, good fellowship and friendly contact are the cornerstones of steady and satisfactory advance, I feel that I bespeak the hearty conviction of each of us, that our association, whether close or remote, with Dr. Amos W. Abbott has been and always will be an elevating influence.

It is my extreme pleasure, therefore, to render you, Dr. Abbott, on behalf of the Minneapolis Surgical Society, while you are still with us in the full vigor of your health and mental faculties, this slight token of our appreciation.

Dr. Fred Olson presented a case of carcinoma of prostate.

The object of this report is primarily to bring before the society the frequency of early metastases along the tract of the thoracic duct in any genito-urinary malignancy; secondly, the apparent absence of local recurrence in the prostatic area. In this specific case, it is now more than three years after operation and there is comparatively complete control of certain secondary growths by radiation along the thoracic duct and its tributaries.

The patient, a male, aged 64, married, chiefly complained of difficulty and urgency in urination. He had had no

previous illness of importance. His general condition has been very good. He has noted increasing difficulty, frequency and urgency in urination during the last six months. No previous treatment. No gross changes noted in the urine.

Examination: Man of 5 feet 4 inches, apparently robust. Head and neck were negative. Heart shows some enlargement with a soft systolic murmur and accentuation of the second aortic sound. Systolic pressure, 180, diastolic 90 mm. Rectal examination shows a bilateral enlargement of prostate of about 2 on a scale of 1 to 4. Consistently uniform firmness throughout. There were 15 ounces of residual urine. The cystoscope revealed the usual picture of a large bilateral enlargement with trabeculated bladder, free from stone or infection. The urine, blood chemistry and phthalein tests demonstrated a moderate kidney insufficiency.

Preparation of patient by gradual decompression for ten days was followed by supra-pubic operation. The enucleation was easy and the wound dry in fourteen days, with an otherwise uneventful convalescence.

Microscopic section of the gland at time of operation was negative for malignancy.

A small area of adeno-carcinoma was demonstrated in the specimen at a subsequent examination seven months later, when an enlarged gland in the left cervical region was noted. The appearance of this gland gave the first indication of the malignant nature of the prostate. No urinary symptoms appeared nor is there any complaint on that score, today, three years after operation.

Cystoscopically the operative area and bladder are negative today.

The usual x-ray and radium therapy was employed locally and along the spine and cervical region.

The patient presents no demonstrable bony metastases. From time to time intense radiation with radium is given along sacral, lumbar and cervical spine with immediate relief of the recurring backache which is the patient's only complaint.

General condition of the patient is very good at the present time.

DR. F. S. BISSELL (speaking by invitation) discussing treatment of Dr. Olson's case:

There is very little I can add except from the standpoint of technic. At the time I first saw the patient, both history and symptoms pointed strongly to metastases involving the retro-peritoneal lymph nodes and extending along the thoracic duct to the left supra-clavicular region. As usual in these cases the pain was constant and quite severe. An interesting and somewhat unusual feature of the case was the immediate relief which he experienced after each radium treatment.

Relative to technic it may be well to emphasize the factor of distance, which is of the greatest importance in cases like this one. By using a block of wood, one inch thick, between radium tubes and skin it is possible to greatly increase the percentage-depth-dose. This point needs to be stressed because there seems to be a rather general impression among medical men that radium technic is not important but that it is only necessary to apply

radium to the skin over the involved areas for a specified length of time.

The patient has not received any treatment for approximately one year and has been wholly free from symptoms or signs of further recurrence.

Dr. T. H. Sweetser presented an interesting case of renal calculus.

This young man is twenty-three years old and single. During the last four years he has had repeated attacks of severe pain in the left flank and lumbar region radiating to the left shoulder and sometimes to the left hip and scro-um. Hematuria, pyuria, nocturia and polyuria have been noted during the attacks. He was first admitted to the Minneapolis General Hospital on July 13, 1923, during a similar attack. Physical examination showed generalized abdominal tenderness with rigidity of the left rectus muscle, tenderness over both kidneys, pain on percussion of both lumbar regions, and rigidity of lumbar muscles. The urine showed pus; leucocyte count was 10,000. Roentgenogram of entire area of urinary tract shows an oval dense shadow about 2 cm. in diameter medial to the lower pole of the left kidney and an irregular group of small shadows in the shadow of the lower pole of the same kidney. As his attack ceased promptly and he had no more discomfort he refused further investigation and treatment and left the hospital on July 20th feeling very well.

On September 5th the ambulance brought him in during a similar, but very severe, sudden attack. The physical signs indicated trouble on the left side only. At that time there was some specific urethritis, and as the patient was promptly relieved of his pain, cystoscopy was not deemed advisable and he was sent to the outpatient department on September 8th for treatment of the urethritis.

His last admission to the hospital was on November 10th during a similar but less severe attack. Cystoscopy on November 21st with the usual local anesthesia of the mucous membranes showed a little puffiness at the left ureteral orifice. An opaque catheter was passed easily up the left ureter, but the other catheter was arrested about 2 cm. from the right ureteral orifice, and attempts to go further with different catheters failed. We felt that this was due to muscle spasm there. Roentgenogram, as you see, showed the tip of the left ureteral catheter touching the lower aspect of the large oval shadow previously seen; when pyelogram was attempted only a very little fluid entered into the renal pelvis. The obstruction was, however, not complete, as we obtained some urine through the catheter; the sample contained a few erythrocytes and many leucocytes. Culture gave no growth.

Another cystoscopy was undertaken on November 26th under caudal anesthesia. Slight edema was noted at both ureteral orifices. Catheters passed easily up both ureters. Specimens showed occasional leucocytes and some erythrocytes. Cultures were negative. Phenolphthalein, given intravenously, appeared through the right side in three minutes and through the left in five minutes. In order to be sure of filling the renal pelvis this time, the patient was tilted back with the head down at an angle of about 45 degrees; the sodium iodide solution was run in by gravity as usual. These interesting pictures were secured.

You see that the left renal pelvis is greatly dilated, the calyces are flattened, and the stone shadows are all obliterated by the iodide solution. The right renal pelvis is slightly dilated but the calyces are not flattened.

Sixteen hours later this other roentgenogram of the entire urinary tract was made. There is no trace of the iodide solution on the right side, but on the left side the stone shadows, especially the small ones in the lower pole, stand out much more prominently than previously because a coating of sodium iodide stuck to them. It has been pointed out by different writers that sometimes a urinary calculus of about the density of the soft tissues may be discovered by just such a procedure, after it has escaped detection in a plain roentgenogram and in a pyelo-ureterogram.

Pyelotomy was performed on this patient on December 3rd by Dr. Oscar Owre. The largest stone was removed intact and smaller soft stones were removed from the lower calyx piecemeal. You may see that his wound is practically healed and that he walks quite well. He left the hospital on January 4th.

In addition to the history of this interesting condition, I wish to emphasize several practical points. First, occasionally an obstruction may be met about 1 cm. from the ureteral orifice, the obstruction being due solely to muscle spasm; second, cystoscopic examination in some patients is greatly facilitated by the use of caudal anesthesia; third, a procedure is described which helped us to secure a pyelogram in spite of a stone obstructing the outlet of the renal pelvis; fourth, the localization of shadows within the urinary passages may be proved by obliterating them with a pyelo-ureterogram, and by the fact that they may be brought into greater prominence in a picture taken a few hours after the pyelogram has been made.

Dr. E. S. Judd, Rochester, presented the paper of the evening. Subject: "Surgery of the Gallbladder." See page 161.

THE REACTION OF THE PARATONSILLAR TISSUES IN TONSILLECTOMY. A STUDY OF THE ETIOLOGY OF POST-TONSILLECTOMY PULMONARY ABSCESS: George Fetterolf, Herbert Fox. (Amer. Jour. of Med. Sc., Dec., 1923.) The authors have shown from a pathological study that the paratonsillar tissue after tonsillectomy is studded with thrombi which may be either sterile or septic, and that as a result of trauma, sepsis and muscular action these thrombi may be dislodged into the

superior caval circulation. Pulmonary emboli are therefore relatively frequent, and may escape notice on account of their small size, sterile character and prompt resolution. As a prophylactic measure they suggest that the routine use of deep transfixion sutures in tying the blood vessels be abolished, and that surface ties be used instead on account of the possibility of infection being carried more easily into the circulation through the transfixion of the thrombi in the vessels.

Inspiratory post-tonsillectomy lung complications are probably not as common as has been thought, and lymphatic transmission of the infection to the lungs they consider extremely rare.

A surgical procedure aiming at a diminution in the morbidity following tonsillectomy consists in their opinion in an intracapsular tonsillectomy as suggested by Makuen. They believe that in its perfected form it will tend materially to reduce the incidence of pulmonary complications following the operation, since the removal of the capsule with the tonsil as done at present removes an excellent bulwark to the infected nidus.

F. J. HIRSCHBOECK.

THE CHRONIC APPENDIX-C: Hamilton Whitehead. (The Practitioner, August, 1922. Page 155.) The author's classification of the diagnosis of chronic appendicitis is a convenient solution of diagnostic difficulties. The symptoms and pathological findings in so-called chronic appendicitis are discussed at length. The writer's conclusions are:

1. The enormous number of patients whose abdominal ailments are now diagnosed as chronic appendicitis chiefly consist of symptoms of widely varying causation and for which symptoms, the appendix is not responsible.

2. The symptoms attributed to the chronic appendix are not explained by the pathological findings and are not cured by removal of the appendix.

3. The operation for removal of the chronic appendix not only fails to cure, but frequently makes the patient worse.

4. Attribution to the appendix of abdominal discomfort of obscure origin hinders investigation into the causes of abdominal pain.

5. In the surgeon, the chronic appendix theory produces laxity in diagnosis and in operating, and incisions are made so small that thorough examination of the abdominal contents is made a mechanical impossibility.

6. In the layman, the operation for the removal of the chronic appendix, because of its failure to cure and because of its after effects, is producing doubt about the necessity for operation in acute appendicitis and mistrust in the bonafides of the surgeon.

7. The chronic appendix theory judged by the test of the ability of the operation for removal of the appendix to rid the patient of his symptoms, is found wanting.

8. In the interest of surgeons and patients the diagnosis of chronic inflammation of the appendix as a condition requiring operation should be abandoned.

MAYO CLINIC, ROCHESTER

RESULTS IN GALL-BLADDER SURGERY: F. N. G.

Starr (Surg., Gyn. and Ob., September 1923). Gall-bladder disease may mean many degrees of inflammation as well as stone formation.

As a life saving measure, drainage or a more radical surgical procedure is considered in the following conditions:

1. Acute inflammation without jaundice.
2. Acute inflammation with cystic duct obstruction.
3. Acute inflammation with rupture of the gall-bladder. (Rare—occurred only three times in 450 cases.)
4. Acute inflammation with so much associated thickening of the duct that obstruction occurs with jaundice.
5. Acute inflammation with common duct obstruction from stone causing jaundice.

The procedure to be followed in these conditions is, first to choose a suitable time, then follow a plan destined to relieve the acute condition, rather than make a brilliant operation. Further restorative measures can be thought of later.

From the economic aspect, distressing symptoms of right costal margin pain with radiation, gas distress, qualitative food distress, constipation, and diarrhea with upper abdominal distress and mucus in the stools should be relieved by operation.

Thirty-two and four-tenths per cent of the author's patients suffered with constipation, and cholecystectomy relieved 72 per cent of them. In cases of diarrhea (29 per cent) the staphylococcus aureus was found in the gall-bladder. Sixty-five and one-half per cent of these have been relieved of the so-called mucous colitis by cholecystectomy.

We should aim to prevent acute conditions, chronic pancreatitis, hemorrhagic pancreatitis, and carcinoma resulting from continued irritation in these cases.

A method of procedure with a medical régime is advisable in some cases, and in others careful pre-operative observation and preparation, proper choice of anesthetic, proper operative technique and postoperative régime is given.

The author closes by stating that if gall-bladder surgery is instituted soon after the first symptoms develop, the mortality is negligible, the disaster of complications is avoided, and the efficiency of the individual as an economic asset is improved, as about 66 per cent of these patients are cured and 34 per cent are relieved of most of their symptoms.

W. P. HERBST.

THE RADICAL OPERATION FOR TERATOMA TESTIS: Frank Hinman, Thomas E. Gibson, Adolph A. Kutzmann (Surg., Gyn. and Ob., Vol. 37, October 1923). This paper is a study of eighty-three cases of testicular tumor in which radical operations were performed, including removal of the lymphatic drainage tissues.

The present radical operation has developed as a result of the work on the lymphatic system of the testicle by Most in 1899. He demonstrated that the primary lymph nodes of the testicle were retroperitoneal along the aorta and vena cava in the lumbar region, at the site of embryological origin.

Pathologically there are two current views. Chevasu maintains that there are two groups—the mixed tumors of the testicle, and a large group of unicellular tumors of malignant nature arising from the epithelium of the seminiferous tubules, called “seminoma.” Ewing states that all testicular tumors are teratomatous in origin, and the authors incline to this view.

The diagnosis of malignancy of a testicular tumor is so difficult and uncertain that any testicular enlargement demands surgical inspection and microscopic study. The growth may be masked by hydrocele. Four cases had a radical operation performed for gummata and massive tuberculosis because a careful examination was not made before proceeding with the radical operation. All ages are affected but most commonly between twenty and fifty. The duration or nature of the tumor does not help in indicating the presence or absence of metastases. There is a relatively greater occurrence of malignancy in cryptorchids.

The prognosis of patients with tumors of the testicle is very poor. The seminoma growth is less malignant than the teratoma. Only about 15 per cent of patients on whom orchidectomy has been practiced have been cured. This fact has led some to advocate radiation as the treatment of testicular tumors, as in some cases it has accomplished phenomenal results.

The operation which the author advises has raised the number of cures by surgery from 15 to about 30 per cent, with an operative mortality of 9 plus per cent.

In treating these cases the operable cases are all treated radically. The inoperable cases, which are made up of the groups in which malignant masses retroperitoneally are fixed and cannot be removed, and those in which masses are palpable through the abdominal wall when examined, are treated by radiation. When these masses are discovered at the time of exploration, radium is inserted at that site, or later through tubes left in as for drainage.

The technical steps of the radical operation are described in detail and illustrated. Briefly they are as follows: positioning of patient with side turned a little to opposite side; incision and clamping of the cord through an inguinal incision; delivery of testicle followed by cautery castration clamp; laboratory examination; extension of incision parallel to twelfth rib. The peritoneum is then separated by incision in the iliac fossa to expose the large abdominal vessels, followed by division and ligation of spermatic vessels at their origin, resection of gland-bearing area from above downward, exposure of retroperitoneal and iliac area to roentgen radiation on operating table, placing of rubber

tubes for drainage, and radium therapy at the back or upper end of the wound.

The author (Hinman) ligated the inferior mesenteric artery in one case in order to make a clean removal of the glands. This patient died of acute cardiac dilatation a few hours after operation, so that the efficiency of the collateral circulation of the human could not be determined. In cats and dogs this artery can be ligated with no bad effect.

The authors have many excellent detail-giving tables on the cases and an extensive bibliography.

W. P. HERBST.

POSTOPERATIVE INFECTIVE PAROTIDITIS: William H. Fisher (Annals of Surgery, Vol. 77, November 1923). Parotitis, following operations on distant parts of the body, is classified according to the severity of the inflammatory process in the parotid gland as follows:

1. Acute parotitis.
2. Acute suppurative parotitis.
 - (a) Circumscribed.
 - (b) Diffuse parotitis.
3. Gangrenous parotitis.

Acute parotitis or simple inflammation occurs usually three to five days after operation. It is characterized by a swelling of the gland and the usual symptoms of any infectious disease. In three or four days this condition usually subsides. Iodine and ice applications are used to most advantage.

Acute suppurative parotitis is characterized by pus formation with an accompanying increase in severity of systemic and local symptoms. Pus can usually be expressed from Stensen's duct when no obstruction exists. Occlusion of the duct by a stone should be ruled out by passage of a probe. A single localized abscess usually recovers by maintaining drainage through Stensen's duct. In cases in which there is a diffuse process the general symptoms are much exaggerated and there is immense swelling of the face, dysphagia, meningeal disturbance, chilling, and leukocytosis.

If there is not free and satisfactory drainage of pus from Stensen's duct the gland should be exposed by a V incision. This incision is made from the zygoma anterior and close to the tragus, down along the sternocleidomastoid muscle. Then a 2½-inch curved incision is made from the mastoid to join the original incision.

These cases that do not do well may have pus burrow to the supraclavicular region, follow the sheath of the vessels to involve the mediastinum or form a retropharyngeal abscess. The mortality in these cases is about 30 per cent.

Gangrenous parotitis is rare, but invariably fatal when it does occur. In these cases all the symptoms are more severe and the pressure of the unyielding parotideo-masseteric fascia causes rapid gangrene. The surrounding structures become involved by the gangrene and death results from septicemia.

The author cites cases to illustrate the different types of parotitis with the proper treatment.

W. P. HERBST.

CHRONIC CHOLECYSTITIS WITHOUT STONE:

Frederic W. Bancroft. (Ann. of Surgery., Nov., 1923.) This is a study of thirty-eight consecutive cases of cholecystitis without stones in which the history, pathology, and late results have been analyzed.

Four methods of infection of the gall-bladder are mentioned as follows:

1. A descending bile-borne infection from the liver.
2. An ascending ductile infection from the duodenum.
3. A hematogenous infection.
4. A spreading infection to the wall of the gall-bladder through the lymphatics from an inflamed contiguous organ.

Twenty-four women and 14 men made up the series of cases. The age at the time of operation was 36 in both men and women, and the average duration of symptoms was $2\frac{1}{2}$ years.

The usual complaint was pain and soreness in the epigastrium or right upper quadrant with indigestion and gas persisting over a considerable period of time. Eleven women and 5 men had had previous operations for lower abdominal inflammatory conditions. Twelve of the patients operated on had definitely diseased appendices, which were removed at operation. This makes 28, or 73.7 per cent, of the cases with associated infection elsewhere.

Upon physical examination the following was found:

Adiposity: Usually moderate amount.

General appearance: Usually not sick.

Tenderness at Murphy's point on deep pressure: Present in 35, absent in 3.

Rigidity: Moderate degree, 9; marked, 4; absent, 25.

Lyon test: Positive in the nine cases in which it was used.

The ante-operative diagnosis in these cases were: Cholelithiasis, 13; cholecystitis, 15; adhesions about duodenum, 4; ulcer of stomach, 2; not mentioned, 2.

Cholecystectomy was done in 31 cases and cholecystostomy in 6 cases. The appendix was removed in 20 cases and found diseased in 12.

The gall-bladders removed were carefully studied microscopically and two pathological types were observed which may or may not have been various stages of the same disease. In one type the mucosa and villi were relatively normal but the submucosa was thickened and there was round cell infiltration in the muscularis and submucosa. In the other type, the so-called strawberry gall-bladder, there were coarsely shaped villi and ulceration of the tips, with scar tissue formation, round cell infiltration, and lipoid deposits in the villi. Boyd found that normal gall-bladders contained 1.70 per cent cholesterol, and that strawberry gall-bladders contained 50 per cent cholesterol.

According to Chauffard small biliary calculi originate inside the villi as minute clusters of cells surrounded by cholesterol. These are shed, then increase in size and ultimately become faceted.

Cholecystectomy resulted in 88.5 per cent cures and cholecystostomy in 50 per cent cures.

The article contains eleven photomicrographs illustrating the normal and diseased gall-bladder conditions.

ROY N. ANDREWS,
MANKATO CLINIC, MANKATO

AN EFFICIENT TREATMENT FOR RESISTANT CASES OF PYELITIS: J. Spencer Davis (Arch. of Ped., October 1923). All authorities are agreed that the disease is much more frequent among females and that the colon bacillus is the most frequent organism found although a mixed infection may be present and occasionally other organisms are the only ones in evidence. In some cases of recurrent pyelitis, specimens of urine obtained by catheter in absence of clinical signs have yielded cultures of colon bacilli. It is apparently in this type of case that an intercurrent affection such as coryza will precipitate an attack of pyelitis. Constipation seems also to play a role at times and the child will escape an attack as long as the bowels are kept active.

Treatment: Some writers prefer alkaline treatment while others alternate urotropin and acid sodium phosphate with alkalis.

Vaccines: For the relief of symptoms, vaccines sometimes play a role but their curative properties are doubtful. For the past ten years injections of whole blood unaltered by anticoagulants was used in the treatment of these cases which did not yield to medication. An attempt was made to determine the smallest quantity of blood which would prove effective. This was found to be 20 c.c. In the severer types of recurrent infections, this was found to be inadequate and larger quantities up to 100 c.c. had to be given. After the injection no medication was given.

Reaction: In some cases it was noted that the patient would have a chill a few hours after the injection followed by profuse perspiration and a fall in temperature, frequently to normal. If the temperature did not reach normal in thirty-six hours, a second injection of blood was given.

Effect on Child's Blood: In a few hours after the injection there is a prompt rise in the leucocyte count, if it is not already high. In some cases, with marked improvement in twenty-four hours the rise in leucocyte count persisted, while in others it declined, especially when there was marked decrease in the number of bacteria in the urine.

Effect in the Urine: In cases showing improvement, the number of bacteria was decreased without necessarily any decrease in the number of pus cells. The pus cells were found in decreasing numbers for several days after the child was clinically well.

Relapse: Out of a group of fifty cases, thirty-five were selected which were followed for from three to five years. These were all severe cases, many of which had had several attacks. In only one was found a recurrence. This case, about two years after an attack which was treated as above, had a recurrence and developed a perinephritic abscess.

R. N. ANDREWS.

AN EFFICIENT TREATMENT FOR RESISTANT CASES OF PYELITIS: J. Spencer Davis. (*Arch. of Ped.*, Oct., 1923.) For the past ten years Spencer has used injection of whole blood unaltered by anticoagulants in the treatment of cases which did not yield to medication. Twenty cubic centimeters was customarily given although in the severe types of recurrent infection larger quantities up to 100 c.c. were given. The greatest number of injections has been five, but in many cases a single injection was all that was necessary. After the injection no medication was given. Occasional systemic reactions occur associated with a definite leucocytosis. Of thirty-five severe cases observed from three to five years, only one relapse occurred.

C. A. STEWART.

THE RELATION BETWEEN CHRONIC TONSILITIS AND ACUTE KIDNEY INFECTIONS: D. Leasesne Smith and C. Williams Bailey (*Arch. of Ped.*, August, 1923). Kidney infections are common complications of the acute infectious diseases, and the primary focus of infection is then a foregone conclusion. But when the primary symptoms are referable only to the kidneys, the case assumes an entirely different aspect. It is generally thought that acute nephritis and pyelonephritis are secondary infections. Also it is generally known that, as in acute rheumatic fever, the symptoms of the secondary infection may completely overshadow those of the primary or the primary infection may be producing no known symptoms. Both primary and secondary infections may or may not clear up spontaneously. In any event, if the primary focus is removed, the secondary trouble will usually disappear if the parts secondarily infected have not been permanently and organically disabled.

Now the tonsils are perhaps the most common avenues of infection; consequently, in a seemingly primary acute nephritis or pyelonephritis, it is logical, first, to suspect that the tonsils are responsible for the entrance of the infecting organisms. If then upon this suspicion the tonsils are found chronically infected and no other focus can be found, it is reasonable to conclude that the tonsils are the primary seat of the disease, the diagnosis being then chronic tonsillitis complicated by acute nephritis or pyelonephritis, as the case may be. In such cases why not immediately remove the tonsils right in the acute stage of the kidney disorder? If in time the acute symptoms subside and the patient recovers, all is well. But if time is allowed, and the kidneys become permanently damaged, the patient may be beyond any help. Many cases of acute appendicitis recover spontaneously, but is it ever advisable to take the chance and wait?

When only the colon bacillus is found to be the infecting organism in acute pyelonephritis, the findings usually indicate less kidney substance involvement and more pelvis inflammation. In these cases the tonsils probably cannot be incriminated as the chief offenders. The more exact method of diagnosis would be to make cultures of the tonsils, blood, and urine. If the organisms are the same in all three, or if tonsils and urine contain the same organisms, the connection is apparent. The removal of the tonsils at the acute stage was well borne by all the cases.

R. N. ANDREWS.

EXOPHTHALMIC GOITER IN CHILDHOOD WITH SOME UNUSUAL MANIFESTATIONS: Henry Heiman, New York (*Amer. Jour. of Dis. of Child.*, September, 1923). Sex distribution shows a definite preponderance of females. The ultimate cause of the disease must act primarily or secondarily through the involuntary nervous system. Heredity has played an important rôle in a large number of reported cases. In none was there any history of syphilis. The structure of the thyroid gland and its pathology have been clearly described by Marine. Uniform enlargement of the thyroid may be produced by a hyperplastic or a colloid gland. In the former, the epithelium is higher and the walls of the alveoli may be thrown up into plications. There is increased blood vessel supply and at times round-cell infiltration of the stroma. The colloid is diminished. In the colloid gland, there is a formation of large amounts of colloid material which stretch the alveolar spaces and produce a flattened epithelium. There is marked thickening of the walls of the blood vessels.

The cardinal symptoms of exophthalmic goiter are tachycardia, exophthalmos and enlarged thyroid gland. The most important diagnostic test is an increased basal metabolism. The exophthalmos is usually less marked in children than in adults, but its presence is generally definitely observed. Graefe's and Stellwag's signs were present in all our cases. The basal metabolism test has proved to be the most important guide in diagnosis as well as in the determination of the severity of the disease. The results in the three cases before treatment were: First case, plus 12 per cent; second case, plus 20 per cent; third case, plus 52 per cent. Clinically, the degree of severity of the symptoms and signs corresponded with the degree of elevation of the metabolic rate. Osler believed tremor to be one of the cardinal symptoms, but in childhood it has not been frequently observed. Alertness and irritability were present in all cases. The mentality of the children was above the average.

In the light of all recent evidence regarding treatment, it seems the most rational procedure to institute first a regimen of strict physical and psychical rest for six to ten weeks. If the patient shows no improvement, a short period of roentgen ray therapy should be tried. Thyroidectomy should be performed if there is no response to the roentgen ray. On account of the toxic action on the heart in the severe cases, it is safer not to wait too long before operation.

R. N. ANDREWS.

CHRONIC ULCERATIVE COLITIS IN CHILDHOOD: Henry F. Helmholz. (*Amer. Jour. of Dis. of Child.*, Nov., 1923.) A careful search of the literature has failed to reveal a single article dealing with chronic ulcerative colitis in childhood. Although different in their mode of onset, when fully developed these cases appear to be the same, the chronic recurring dysentery with watery, bloody passages, marked emaciation, persistence of the symptoms in spite of treatment, and the absence of any known etiologic factor. Chronic ulcerative colitis, as defined by Logan, is a chronic inflammation of the large bowel, of unknown etiology, and showing all grades of inflammation, from a reddened, congested, easily bleeding mucous membrane, to

superficial and deep ulceration, with constant or recurring dysentery, lasting from many months to several years.

So far as is known, there is no single definite etiologic factor in chronic ulcerative colitis. The condition may be the result of a variety of infections, pyogenic, dysenteric, amebic or tuberculous; but wherever a specific cause can be demonstrated, the condition is usually not considered chronic ulcerative colitis.

The ulceration begins in the lower portion of the bowel, and in the course of the illness the entire colon is involved. Only rarely is the ileum involved. On proctoscopic examination, the ulcers are usually most marked in the rectum and lower sigmoid, and in the early cases become less numerous in the sigmoid. The colon is usually thickened, the surface appearing red and glazed, with numerous small ulcers. In the severe cases, only small islands of mucosa are left, the entire surface being ulcerated, and presenting a granular appearance. The roentgenogram is characterized by marked narrowing and absence of haustrations in the full extent of the involved colon. Large hemorrhages occur only occasionally in the adult, but seem to be more frequent in the child. If there is no complication, the patients are usually free from fever.

Under medical treatment, the outlook is bad. Logan gives a mortality of 7.5 per cent in his cases. All of the four patients in the series did poorly under medical treatment alone, and only two improved after surgical intervention. In two cases a colostomy, in the third an appendicostomy, and in the fourth an ileostomy (Brown operation) was performed, by means of which the lower bowel could be constantly irrigated with saline solution. Recently Logan has reported several cases in which the patients improved markedly under massive doses of iodine by mouth. If the patient does not improve in the course of six weeks or two months, under medical treatment, it is advisable to operate. The operation of choice is unquestionably the one devised by Brown, consisting of an ileostomy with the establishment of a complete fecal fistula, through the lower loop of which the colon can be irrigated.

THE TREATMENT OF GONORRHEAL ENDOCERVICITIS BY HEAT: Budd C. Corbus and Vincent J. O'Connor. (*Surg., Gyn. and Ob.*, Vol. 38, January, 1924.)

Many methods have been tried for the cure of gonorrheal endocervicitis. Failure has been due to a lack of definite knowledge of the pathology and inaccessibility of the affected parts to topical applications.

Curtis has shown by histological and cultural examina-

tions: the infrequency of chronic endometritis; the rarity of gonococci in fallopian tubes removed from patients free from leucocytosis and fever for a period of ten days or two weeks; sections of cervixes very frequently show gonococci.

Persistent tubal gonorrhea results from the recurrence of an infection from without or more commonly from repeated invasions from a chronic lower genital tract infection.

Gonococci localize in the cervical glands and are the predisposing cause of purulent endocervicitis and leucorrhea.

Utilizing the well-known fact that gonococci are instantly destroyed at a temperature of 113° F. (45° C), the authors have devised an electric thermophore for introduction into the cervical canal. By this device a constant temperature of 116°-117° F. is maintained for 30-40 minutes without pain or discomfort to the patient. Treatments are repeated at seven or ten day intervals. The treatment causes a rapid healing of cervical erosions and the purulent cervical discharge quickly assumes a watery character. Treatments are continued until the gonococcus is absent from five successive smears.

After an elapse of two months, 5 per cent silver nitrate is applied endocervically. With two negative smears the patient is pronounced cured.

In twenty-two cases the gonococcus disappeared permanently from the cervical discharge; after one treatment, five cases; two treatments, seven cases; three treatments, four cases; four treatments, two cases; seven treatments, four cases.

Contraindications to treatment are pregnancy, acute pelvic cellulitis and salpingitis.

ROENTGENOLOGY

SUPERVISORS:

LEO G. RIGLER,

MPLS. GEN'L HOSPITAL, MINNEAPOLIS

A. U. DESJARDINS,

MAYO CLINIC, ROCHESTER

PULMONARY ABSCESS ROENTGENOLOGICALLY CONSIDERED: W. H. Stewart (*Jour. of Radiology*, Page 277, August, 1923). The causes of pulmonary abscess in the order of their frequency are tonsillectomy, pneumonia, lobar or lobular, other operations, inhalation of foul water while bathing, sacculated empyema breaking through the visceral pleura. A primary abscess may occur with pneumonia as a secondary manifestation.

Most abscesses may be diagnosed clinically. The x-ray is chiefly valuable for localizing the abscess, determining its extent and the presence of associated lesions. The early appearance is that of an oval-shaped localized pneumonitis. With the development of cavitation a lighter area appears within the zone of infiltration. The cavity may be filled with fluid giving a homogeneous shadow; or it may be partly filled showing a fluid level.

Roentgenologically, the most common mistakes are the diagnosis of one abscess when there are a number of smaller ones; and diagnosing abscess when sacculated empyema is actually present. The latter can best be distinguished by the absence of foul sputum. Air bubbles appearing in an encapsulated empyema may be due to a bronchial fistula or to needling. Tuberculous cavities can be distinguished by the lack of infiltration about them, their position, the laboratory findings and the presence of other areas of tuberculous infiltration. Sarcomata are very difficult to diagnose.

The author advises drainage by means of repeated bronchoscopy as the best form of treatment. If necessary injections of silver salts or bismuth subcarbonate suspended in sweet oil should be given. Frequent roentgen studies, with the patient in the prone lateral position and the tube posterior, should be made to check the results of treatment. The cases with much infiltration and little softening do not respond well to bronchoscopic treatment and surgical intervention is advised. The abscess must be accurately localized for the surgeon and is best done with the hand fluoroscope on the operating table, to avoid the errors which result from slight changes in position or in phase of respiration.

LEO G. RIGLER.

LOCAL RESISTANCE TO SPONTANEOUS MOUTH CANCER INDUCED BY X-RAYS: J. B. Murphy, J. Maisin, E. Sturm (Jour. Exper. Med., Vol. 38, p 645, November 1923). In a previous paper, Murphy and his co-workers have shown that an erythema dose of x-rays given over an area of skin renders this area highly resistant to inoculation with transplantable cancer. To make this work more convincing, further experiments were done using auto-grafts from spontaneous mouse tumors. The tumor was removed from the mouse and an area in the flank was exposed to an erythema dose of x-rays. Portions of the removed tumor were then inoculated in both flanks of the same mouse. On the radiated side there were 16 per cent takes, while on the non-radiated side 71 per cent of the grafts grew. All the growths which did occur on the radiated side were smaller and slower growing than those on the non-radiated side. Two further sets of experiments were done using the same experimental and control methods. These showed that radiation of the tumor cells themselves, either in vitro or in situ after transplantation, did not hinder their growth or prevent transplantation, if immediately transplanted to a different non-radiated area. The work was done on enough cases and with sufficient controls to warrant careful consideration of the results. These indicate that the retardation in growth and the destruction of mouse tumors, which occur after an erythema

dose of x-rays, is not due to the specific effect upon the tumor cells, which is generally believed, but rather to an effect upon the normal tissues in which the tumor is implanted. The authors do not believe the results of x-ray therapy on cancer can be due to greater susceptibility of tumor cells, but rather to the change induced in the tumor bearing tissue.

LEO G. RIGLER.

PERICARDITIS WITH EFFUSION: Hodges (Jour. Rad., October 1923). Acute pericardial effusions are most often due to acute articular rheumatism, pneumonia, or other infections. Chronic effusions are uncommon and are most often due to tuberculosis. The fluid may vary in amount and may be serous, sero-fibrinous, sero-purulent, or hemorrhagic. Pain is the chief symptom and the pericardial friction rub is the chief diagnostic point in small effusions. The author considers the only physical signs of value in the larger effusions to be, the friction rub, extension of the cardiac dullness upward on the left, substernal dullness changing with change in the position of the patient, broadening of the cardiac area, signs of compressed lung at the angle of the left scapula, and pushing down of the left lobe of the liver. Roentgen examination is useful, when there is more than 200 c.c. of fluid, to determine the presence of fluid, its extent, location for paracentesis, and to distinguish pericardial effusions from pleural effusions and from consolidations of the lung. There is a difference of opinion amongst clinicians and roentgenologists as to the value of the roentgen ray, especially in distinguishing pericardial effusions from dilated hearts. The author studied sixteen cases of pericardial effusion, in five of which the diagnosis was not made by the roentgenograms. In four of these there was less than 200 c.c. of fluid. The findings were as follows: widening of the mediastinal shadow; a bulging of this shadow upward and to the left; widening of the heart shadow; obliteration of the curves of the borders of the heart; extension of the mediastinal borders as more or less straight lines up to the clavicles; change in the contour of the cardiac shadow with change in the position of the patient; weakened cardiac impulse. In the presence of adhesions the mediastinal shadow may show little change. In the presence of large pleural effusions the diagnosis may be difficult. To differentiate it from dilated heart, mediastinal effusions and tumors, the most valuable sign is the change in the contour of the heart with change in position of the patient. The diagnosis is of importance as paracentesis may be a life saving measure. Negative diagnoses in the presence of fluid are more excusable than positive diagnoses in the absence of fluid.

LEO G. RIGLER.

GENERAL MEDICINE. Vol. I. The Practical Medicine Series. Edited by George H. Weaver, M.D., Lawrason Brown, M.D., Robert B. Preble, A.M., M.D., Bertram W. Sippy, M.D., Ralph C. Brown, B.S., M.D. Series 1923. Chicago: The Year Book Publishers.

The 1923 Volume of General Medicine in the Chicago Practical Medicine Series conforms to its past high standards. Perhaps the most valuable single asset in this review is the accuracy and brevity with which the various subjects are handled. There are some outstanding features that deserve special notice. The article on diseases of the blood is very interesting. The pathogenesis of pernicious anemia receives considerable attention, but progress in this direction does not seem to have been made. The suggestion that reactions following blood transfusions may be allergic is arresting and within the last year has received more and more attention. Perhaps one of the most readable reviews in the volume is the one showing clinical charts which are recommended by the Association for the prevention and relief of heart disease. These are worth careful study and their use would probably do much to eliminate the occurrence of cardiac lesions. There is a review of the treatment of asthma which does not advance our knowledge of this subject much further than it has already been done by Walker and others.

One would like to pick out further examples of concise narration covering interesting facts recorded in the past year; these, however, merit a direct reading of the volume. The few instances recorded above have been given with the hope that they would awaken interest in the book itself.

SYPHILITIC AORTITIS*

FREDRICK A. WILLIUS, M.D.

AND

ARLIE R. BARNES, M.D.

Section on Medicine

Mayo Clinic, Rochester, Minnesota

The predilection of syphilis for the arterial system, especially the thoracic aorta, is a well established fact, and has been the subject of much interest and endeavor. The advent of modern methods of diagnosis, such as roentgenography and the Wassermann test, have certainly contributed to a greater degree of accuracy in diagnosis, yet they have not fully solved the problem of identifying syphilitic disease of the aorta. The general tendency in modern medicine, unfortunately, has been to place too much emphasis on laboratory methods in the diagnosis of disease. It is not our intention to depreciate the value of the newer methods; we wish rather to emphasize the importance of recognizing them as valuable adjuncts, and to invite attention and interest again to the old, well established methods of physical diagnosis. No one method of diagnosis is infallible, and accuracy, therefore, depends on the intelligent interpretation and evaluation of all methods.

The syphilitic lesion is commonly on the ascending aorta, then on the arch and descending aorta. Klotz's excellent experimental studies and observations have explained many of the problems dealing with syphilitic disease of the aorta. He has shown that the lymphatic supply of the aorta is not uniform, in certain regions the lymphatics are present in great numbers, while in other regions the distribution is meager. The ascending aorta appears to have lymphatics in common with the pericardium, and also communications with a group of nodes that join the lymphatics of the anterior medias-

tinum. Around the arch of the aorta are found lymphatics supplying the aortic wall. These connect with nodes in the anterior mediastinum, with those around the right and left border of the trachea, and with those at its bifurcation. The descending aorta has a variable number of lymph nodes, particularly along its right border, which form a plexus around the exit of the intercostal arteries. This lymphatic system is in direct communication with the two large drainage beds of the body, the one in the thorax and the one in the abdomen. These observations certainly clarify the problems of regional localization of syphilitic lesions on the aorta.

Klotz has shown further that the *Spirocheta pallida* attacks the aorta by way of the small lymphatics accompanying the vasa vasorum. The infection enters from without, and occurs first in the adventitia, with resulting periaortitis. This accounts for the common observation of cohesion of the aorta with the surrounding structures. The early involvement of the adventitia has significant bearing on certain of our succeeding remarks and observations. The periaortitis is then progressively followed by involvement of the media (mesoaortitis) and of the intima (endoaortitis). The pathologic changes of syphilitic aortitis are so well known that a detailed description here is unnecessary, except for the statement that the inflammation is productive in character, with a tendency to reparative fibrosis and resulting deformity. The cicatricial fibrosis has a definite bearing on the progression of the symptoms and on the objective findings of the disease; this will be emphasized later.

One hundred forty patients with syphilitic disease of the aorta were observed by us for a period of from one to eight years. The patients have been studied in three groups, according to the degree of apparent damage which fairly accurately divides the course of the disease into clinical periods: (1) early stage, (2) moderately advanced stage, and (3) advanced stage.

*Read before the Minnesota State Medical Association, October, 1923.

Early Stage.—The early stage of syphilitic aortitis comprises cases in which the characteristic objective findings of aortic disease is lacking, namely, the absence of appreciable cardiac enlargement, murmurs, vascular phenomena of aortic regurgitation, and dilatation of the aorta. Ten of our patients, seven males and three females, were classified in this group. One patient was in the third decade of life, two in the fourth, four in the fifth, and three in the sixth. The marked dominance of males was noted also in the other groups, and supports Stokes' opinion of a relatively increased immunity in women against syphilitic infection. The age of the patient is an important factor, as undoubtedly many years elapse before the disease is evidenced by symptoms. In this group the average time from the occurrence of the primary lesion to the initial examination, was seventeen years. Three of the patients when first examined had no symptoms referable to the cardiovascular system, five had mild dyspnea and palpitation with exertion, and two had typical anginal attacks.

Quite early in our experience with cardiovascular syphilis, we noted that occasionally a patient was encountered in whom the characteristic objective findings enumerated were absent, but in whom a peculiar tambour-like accentuation of the aortic second tone was audible. This peculiar tympanitic accentuation was usually quite well localized to the aortic area, but at times was heard also to the left of the upper sternum. Our first impression was the anticipation of finding hypertension, but sphygmographic studies failed to confirm this supposition. The first patient in whom this peculiar change in the character of the aortic second tone was noted, was repeatedly under our observation during the time she was receiving rigid treatment for syphilis. At the end of nine months a rough, reverberant systolic murmur was audible at the aortic area, and transmitted into the carotids. At the end of two years this patient had the classical signs of aortic regurgitation besides the systolic murmur, and the tambour-like accentuation of the aortic second tone was lost. We have observed this same progression of events in five other cases.

The peculiar character of the second tone was described years ago by Potain, and again emphasized by McRae and by Longcope, but the phenomenon has apparently attracted little attention recent-

ly. The probable mechanics of this distinctive aortic second tone is interesting and logical, in view of Klotz's work. If the fact is recalled that the primary involvement of the aorta occurs in the adventitia and media, one can readily appreciate that these changes will cause alterations in the elasticity or resilience of the aorta, not only through fibrotic changes in the adventitia, but by cohesion of the aorta to contiguous structures. This diminution in the elasticity of the aortic wall in the presence of a competent aortic valve necessarily increases the resistance against the inrush of blood from the heart, which in turn increases the intra-aortic tension and causes rather forcible closure of the semilunar leaflets. This finding cannot, of course, be interpreted as indicative of the presence of periaortitis alone, since undoubtedly the other layers of the aorta may sometimes be involved. We believe that this peculiar tympanitic accentuation of the aortic second tone, in conjunction with other evidence of syphilis, justifies the diagnosis of early syphilitic aortitis. It is so different from the changes accompanying hypertension and atherosclerosis of the aorta that these should not be confused with it. In the latter conditions the second tone is usually accentuated but has a metallic character, or else its quality is not altered, but simply intensified.

In two only of the ten patients did the roentgenograms reveal dilatation of the aorta, and in both instances the dilatation was slight. We have repeatedly been disappointed in the failure of roentgenography to aid us in the early diagnosis of disease of the aorta.

The blood Wassermann reactions were strongly positive in nine patients and negative in one. Three patients had associated syphilitic lesions; one had syphilis of the central nervous system with positive serologic changes in the spinal fluid; one had osseous syphilis, and the patient having the negative blood Wassermann reaction had typical cutaneous syphilis, which was cured completely under treatment. Electrocardiography is of little diagnostic value in these incipient cases; in only one of the entire group were there significant alterations in the graphs, consisting of negativity of the T wave in Derivation I. This patient had angina pectoris.

Five of the ten patients were traced. The condition of three is worse, of one unchanged, and of one improved; none is dead.

Moderately Advanced Stage.—The patients who have been classified for study in the moderately advanced stage of syphilitic aortitis, are those whose examination revealed systolic murmur, usually quite well localized to the aortic area, invariably rough and reverberant in character, and frequently transmitted into the carotids. In about half of the cases the aortic second tone was accentuated, but did not have the peculiar tambour-like quality we have described. There were thirty patients in this group, nineteen males and eleven females. One patient, with typical hereditary syphilis, was in the first decade of life, one was in the second decade, one in the third, seven were in the fourth, eleven in the fifth, twelve in the sixth, and two in the seventh. An average of twenty-one and one-half years elapsed between the primary lesion and our examination.

Six of the thirty patients had no complaints referable to the cardiovascular system, thirteen had varying degrees of dyspnea, palpitation, and other symptoms indicative of an inefficient heart, and eleven had angina pectoris; this latter group will be considered more in detail later. The systolic murmur, with its peculiar reverberant quality, is probably due to the intimal roughening indicative of moderately advanced aortic syphilis. In three cases only did the roentgenograms reveal even slight to moderate dilatation of the aorta, while in many cardiac enlargement was noted.

The blood Wassermann reactions were strongly positive in fifteen patients, negative in twelve, and not recorded in three. The spinal fluids of six patients were serologically positive, and of these, three had negative blood Wassermann reactions; the reaction was not recorded in one. Thus eighteen patients in the group had serologic signs indicative of syphilis. Twelve patients had syphilis besides the cardiovascular involvement; eight of these had syphilis of the central nervous system, two of the osseous system, one of the skin, and one of the liver.

The electrocardiograms of only three patients revealed significant abnormalities. These consisted of T wave negativity, in one case involving Derivation I, and twice affecting combined Derivations I and II. Two of the patients had angina pectoris and the other, severe attacks of paroxysmal dyspnea, conforming to the old entity formerly termed angina pectoris sine dolore.

Eighteen of the thirty patients were traced. Four

report their condition to be worse, six unchanged, and two improved. Two patients died of heart disease, an average of fifteen months after our initial examination. Four patients died of other causes.

Advanced Stage.—Patients whose syphilitic aortitis had progressed to the development of aortic regurgitation were classified as being in the advanced stage. It is needless here to review the classical signs of this lesion. Aneurysm of the aorta, of course, is a manifestation of advanced aortic syphilis, but has not been included in this study since it warrants more consideration than the scope of this presentation will permit. There were 100 patients in this group, of which eighty-eight were males and twelve were females. Three patients were in the third decade, eighteen in the fourth, forty-seven in the fifth, twenty-seven in the sixth, and five in the seventh. An average of twenty years had elapsed from the time the primary lesion appeared until our initial examination.

No one of the patients was free from cardiovascular symptoms, sixty-three had dyspnea, palpitation, and so forth, and thirty-seven had angina pectoris. It is well known that the syphilitic process in the aorta is retrogressive as well as progressive, and that involvement of the aortic valve is almost inevitable in an advancing process. Aortic regurgitation occurs either from cicatricial deformity of the aortic ring, or valve leaflets, or from dilatation of the ring from the associated involvement of the aorta itself. The loss of the accentuation of the aortic second tone or its utter disappearance in the presence of aortic regurgitation, is due, of course, to the failure of the valves to approximate. Occasionally the second tone is accentuated, and such accentuation is the result probably of sclerotic changes of the valves favoring sound production. The roentgenograms revealed aortic dilatation in eighteen patients, in six of whom it was aneurysmal.

The blood Wassermann reactions were strongly positive in seventy-two patients, negative in twenty-five, and not recorded in three. The spinal fluid of fifty-five patients was studied; syphilis was indicated serologically in eighteen, the studies were negative in thirty-seven. Two patients with negative blood Wassermann reactions had positive reactions on the spinal fluid, thus the total serology in this group was positive in seventy-four instances. Twenty-four patients had associated syphilitic lesions, and of these twenty-three had syphilis of

the central nervous system, and one a tertiary lesion of the mucous membrane.

The electrocardiograms of thirty-four patients revealed significant changes, chiefly significant T wave negativities as follows: eight patients had T wave negativity in Derivation I, seven T wave negativity in combined Derivations I and II, nine had T wave negativity in combined Derivations II and III, and in eight patients all the derivations were affected. One patient, besides having the T wave negativity in Derivation I, had QRS complexes aberrant in all derivations. One patient had auricular fibrillation. One of us⁸ previously emphasized the infrequency of auricular fibrillation in aortic disease, in a study of 500 patients with auricular fibrillation disclosing only thirteen aortic lesions. Eighteen of the thirty-four patients with significant T wave negativity had angina pectoris.

Sixty-four of the 100 patients were traced. Thirteen were worse, thirteen unchanged, and six improved. Thirty-one had died of heart disease an average of fourteen months from the time of examination. One patient had died, but the cause could not be ascertained.

PAIN WITH SYPHILITIC AORTITIS

A discussion of the character of the anginal attacks attending syphilitic aortitis is warranted here, since the origin of pain and its distribution are often bizarre. Fifty of the 140 patients in this series had had anginal attacks. Six patients had typical attacks, consisting of severe retrosternal pain, radiating into the left arm, and precipitated by exertion. Twenty-five patients had attacks of severe retrosternal pain without radiation following exertion. Two patients had retrosternal pain, radiating through to the back, to the right side of the neck, and into the right arm, and one patient had pain in both shoulders, radiating to the elbows, brought on by exertion. One patient had pain in the left arm from the shoulder to the elbow with exertion. Three patients had a sense of chest oppression without pain, coming on with exertion. A certain group of cases represented more unusual pain distribution, and are similar to those previously reported.⁹ Five patients had severe middle epigastric pain without radiation, induced by exertion, three had epigastric pain radiating into the chest and into both arms, and one had epigastric pain radiating through to the back, neck, shoulders, and chest following exertion. One patient had

pain in the upper left abdomen without radiation. In one instance the pain started in the dorsal region of the back, and radiated to the right shoulder and arm. The frequency of atypical pain manifestations in syphilitic aortitis, emphasizes the importance of careful questioning in obtaining histories of diagnostic value.

GENERAL DISCUSSION

The classification adopted for this study is purely arbitrary. It has been based on objective findings to enable us to stress the importance of physical diagnosis, an art which, regrettably, is becoming unpopular. We have already conceded that this classification may not always coincide with the findings of the pathologist with regard to degree and extent of involvement, yet it enables the clinician to group his cases according to apparent damage.

It is important to realize that a long period elapses from the appearance of the primary lesion of syphilis to the onset of symptoms indicative of invasion of the aorta. In this study the average time elapsing from the time of the appearance of the primary lesion to the time of our initial examination was nineteen and one-half years, and in most instances symptoms referable to the cardiovascular system had been present but a few years. It is essential, therefore, always critically to search for cardiovascular involvement in cases of syphilis, and persistently and repeatedly to examine such patients over long periods.

We wish briefly to recapitulate the results of some of our special laboratory methods. The blood Wassermann reactions were strongly positive in ninety-six of the patients, and the spinal fluids of twenty-four of the patients indicated syphilis. In five patients in whom the blood Wassermann reactions were negative, the spinal fluids were positive; the total positive serology was 101 (72 per cent). Larkin and Levy reported positive Wassermann reactions in 90 per cent of patients with syphilitic aortitis demonstrated histologically whose syphilis had existed for about fifteen years. Some of their patients may have been free from objective clinical signs of syphilitic aortitis, thereby bringing the percentage of positive reactions higher. In only twenty-one of the patients did the roentgenograms reveal dilatation of the aorta.

From the foregoing data it is obvious that neither Wassermann reaction nor roentgenography is infallible in the recognition of aortic syphilis. On

the other hand there was no instance in this study in which physical diagnosis failed to reveal evidence indicative of disease of the aorta. These results, we believe, entirely justify our stand in emphasizing the importance of physical diagnosis, which must always rank with the subsidiary yet valuable laboratory adjuncts.

Electrocardiography is helpful only in corroborating advanced disease of the aorta, especially when cicatricial fibrosis has involved the coronary orifices. The most common graphic abnormalities encountered in our cases were significant T wave negativities, occurring in thirty-seven patients; twenty-one of these had angina pectoris. One of us¹⁰ has previously emphasized the frequency of these graphic changes in angina pectoris, presumably due to coronary sclerosis. Our findings in this study also favor the concept repeatedly expressed, that T wave negativity results from myocardial effects produced by changes in the circulation of the heart itself.

In the advanced stage of aortic syphilis particularly, even during intensive treatment for syphilis, subjective, objective, and graphic evidence of progression may often be observed. We have repeatedly noted the onset of anginal attacks, or seizures of paroxysmal dyspnea, and the development of significant T wave negativity in the electrocardiogram. Two possibilities are at once suggested: (1) in advanced aortic syphilis the damage and deformity are so marked in many instances that progression occurs in spite of rigid treatment, and (2) when treatment is effective in controlling the syphilitic process, the resulting reparative fibrosis produces deformity leading to progressive cardiovascular impairment. This is especially true in the atresia of the coronary orifices, often observed at necropsy, when the effect on the heart is identical to that produced by obliterative arteriosclerosis of the coronary arteries themselves.

In the early stage of the disease no cardiac deaths occurred. In the moderately advanced stage, cardiac deaths occurred in 11 per cent of the patients, while in the advanced stage, heart disease produced 48 per cent of the deaths. The total cardiac mortality was 38 per cent.

It is important in this connection that, of the thirty-seven patients having significant T wave negativity in their electrocardiograms, eighteen (49 per cent) have died of heart disease; in other words, 55 per cent of the total cardiac deaths oc-

curred when these changes existed. We have repeatedly called attention to the serious prognostic significance of this graphic abnormality.

We believe that we have submitted data that emphasize the necessity for and the importance of the early recognition of aortic syphilis. The fact that only ten (7 per cent) patients with early syphilitic aortitis were found in this study, that thirty (21 per cent) were in a moderately advanced stage of the disease, and 100 (71 per cent) had advanced aortic involvement, indicates that the early recognition of aortic syphilis is not frequent. Tuohy, in a comprehensive review of aortic disease, has also called attention to the necessity of its early recognition. The frequency with which cardiovascular syphilis is noted, indicates that more intensive and prolonged treatment of all patients with syphilis is necessary, since the prevention of cardiovascular involvement implies, of course, an arrest of the etiologic disease before permanent and irreparable vital damage shall occur.

DISCUSSION

DR. JOHN A. STOKES: As a student of syphilis watching Dr. Willius' almost uncanny instinct for the earliest signs of aortitis, I have come to appreciate the immeasurable value of expertness in physical diagnosis in the early detection of this, the gravest complication of syphilis. As he says, the ear and not the blood Wassermann reaction or the x-ray,

detects the earliest sign of syphilitic aortic disease. The average diagnosis of syphilitic aortitis is made many years too late for favorable therapeutic results, although by a proper selection of cases even then a presentable showing may be made. Mortality statistics now being collected appear to err in applying new methods for detecting failure to old notions of case selection, making the outlook seem unduly black.

Observation for an aortic lesion should begin in every syphilitic by the second year of his infection regardless of blood findings. The expert opinion of a cardiologist is invaluable in patients who present relapsing or persistent positive blood Wassermann reactions. We should treat latent syphilis within the first two decades of the disease, even though the positive blood Wassermann is the only sign. The vascular involvement which may be present may not be detected until much damage has been done. One should not be misled into overlooking the vascular system because the patient offers some other presenting symptom of syphilis and makes no vascular complaint. In addition to careful physical examination it is well to question syphilitics closely in regard to precordial strain on exertion and shortness of breath, to which they may have given little attention. I know I seem radical, but I believe we should treat vigorously for syphilis, young men with aortic systolic murmurs even in the absence of the grossly obvious history or findings of syphilis, provided a reasonable case may be made out for exposure to the risk of acquiring the disease. At least no harm will be done and often much good. Think of rheumatism late rather than early among the possibilities and give mercury, iodides and arsphenamine the preference over tonsillectomy as a therapeutic test.

That periaortitis is the principal pathologic change in early syphilis of the aorta is shown by therapeutic tests on supposed solid tumors of the mediastinum which develop aneurysmal pulsation with disappearance of symptoms under treatment.

Accentuation of physical signs and even apparent progress of the lesion may take place in treating early syphilitic aortitis. A therapeutic paradox unfolds under your ear, in that the patient with a tambour second sound develops a murmur as healing sclerosis stiffens his aorta and distorts his valves. A patient with a systolic murmur may develop a diastolic bruit and slight temporary decompensation as treatment takes effect. Such signs are confirmatory and observation shows the process to be arrested, not progressive.

Vigorous treatment with mercury and iodide for weeks, followed by arsphenamine in early cases without marked coronary sclerosis or myocardial degeneration, yields excellent results. Arsphenamine is often disastrous in patients with pronounced symptoms of coronary obstruction such as severe and long standing angina pectoris, or with the electrocardiographic evidence of myocardial damage mentioned by Dr. Willius. Death of the patient from the healing of his lesion is the therapeutic paradox which follows the obliteration of a diseased coronary artery by the too rapid effect of modern treatment. Exceptional late cases may through localization of the process high in the aorta escape coronary occlusion and may respond well to intensive measures. We should in general select cases on

the basis of coronary symptoms and electrocardiographic signs, not merely Wassermann tests.

DR. HENRY L. ULRICH, Minneapolis: I am glad Dr. Willius brought this subject up for discussion. Twenty to thirty years ago when they were treating syphilis by waiting until the secondaries appeared, the number of aortitis cases must have been larger than today. Chronic syphilis today has a more subtle aspect than in those days because of the improved therapy. Likewise we must approach the diagnosis of aortitis in a more subtle manner. The physicians of the older schools are to be admired for many things. They knew and recognized aortitis. One of their admirable qualities was their reliance on their eyes, their ears, their hands. We have had the tendency to drift away from fundamental clinical methods and depend on laboratory diagnoses. In aortitis particularly we must get back to the education of our eyes, our hands, and our ears. And the more delicately we train these organs the earlier will be our diagnosis of this disease.

It would be very interesting to know the percentage of aortitis present in the syphilitic clinics today. It would be interesting to check up the therapeutic efficiency of these clinics by the number of patients with aortitis in later years. As the years go by, syphilitic aortitis ought to be a vanishing disease if our therapeutics is correct. Again, how many syphilographers ever warn their patients of the possibility of aortitis or even think of the aorta in the problem of a syphilitic case. Yet syphilitic aortitis is a common finding in visceral syphilis at necropsy.

Clinically it has not been stressed that there are four groups of this disease: aortitic, aneurysmal, anginal and cardiac (or valvular). In the cardiac there is the "silent type" in which there are no symptoms referable to the heart. In the cardiac group when there is decompensation the heart rarely comes back; it is the beginning of the end. This is an interesting point and differs in this particular from the rheumatic type of aortic disease.

DR. EDWARD L. TUOHY: This subject of aortitis has interested me for a long time and while there is a great deal that might be said on the subject I think we should confine our attention rather definitely to the points brought out so very well by Dr. Willius. It is very evident from this study and any other study that has been carefully done that early aortitis is largely overlooked and has to be surmised. We know (and it places a heavy responsibility on us) and realize that these late manifestations of aortitis mean that these patients have had something very definite there long before, but we were unable to discover it.

Applying ourselves to the ten per cent and to the definite recommendation made by Dr. Willius that we pay special attention to this exaggerated second aortic tone, I agree with that very heartily. Clifford Alburt refers to it as the "bruit de taburka" and gives the credit for the elucidation to Potain. Tones of any sort are subjective. If we could reproduce these notes so as to vivify them externally we would have something that is not made within our own heads, for comparative study. However, it is only by the keenest education of the ear that this particular tone may be differentiated from various other accentuations. It is difficult and it must come largely through personal experience.

While we are on that point, Hoover, of Cleveland, has had much to say relative to his personal ability to diagnose early aortitis by percussion and that introduces again the personal factor, which is, on the whole, most undeterminative. He also draws attention to this fact that anything that will pull the lung away from the aorta in that region will bring the aorta closer to the chest wall and will therefore accentuate that tone. That is exactly what we get occasionally with apical tuberculosis on the right side and I have seen this phenomenon. That is one place where you would have to be cautious as to whether you have tambour tone or not.

In the second and larger group systolic murmurs should be the subject of careful study because systolic aortic murmurs are usually due to the intimal atheroma and this intimal induration has nothing to do with syphilis. So it is well to point out that wherever we have evidence of general atherosclerosis (eye grounds—peripheral arteries, etc.) we should make these deductions with great care. The young individual with angina (definite angina, before forty-five) will probably, if you observe them long enough, develop syphilitic aortitis and the classical phenomena that go with it. The development of the various other signs are unfortunately all too common.

Regarding the Wassermann test: I have followed a number of individuals in whom I made the proper surmise that they had syphilitic aortitis and did not have the courage to substantiate it definitely because they had a negative Wassermann test. I have watched these patients come back later and they have had definite aortitis. This paper placed the whole matter definitely before us. Certainly we have no easy short-cut to eliminate the difficult problems in early diagnosis as presented in this field.

DR. C. N. HENSEL: There are two or three points that should be emphasized in this excellent paper of Dr. Willius. The first is the fact that his statistics, corroborating other statistics, show about 74 per cent positive Wasser-

manns in the presence of active aortic change. The second is that his group of early cases, which are the important cases to diagnose—because that is the time when treatment is most effective—was only 10 per cent. The third is that he finds the early stages of aortitis are given scant attention. We can easily discover aortic aneurysms or an aortitis with heaving of the arch of the aorta and the more marked signs. These are the cases we may all recognize, but the cases we *should* recognize are the 10 per cent that Dr. Willius tells about; but, as Dr. Tuohy has said, the absence of a positive Wassermann test makes us fearful of going ahead in the treatment of these suspected cases.

I first saw a man, 45 years old, five years ago, whose symptoms were throbbing heart, sternal oppression, weak heart tones and lack of physical endurance, with a large flabby heart, wide at the base. I looked at him through the fluoroscope, but could see no pulsation of the aorta. He had five negative Wassermanns and had three more in other clinics. In 1920 somebody began to give him arsphenamine and mercury. I recently looked at his heart under the fluoroscope and now he has a most beautiful pulsating aneurysm of the descending thoracic aorta, with a heart beat of seventy-two, an increase in his physical endurance and apparently the lesion is perfectly compensated. He has had continuous treatment from 1920 on. This man has never had a positive Wassermann. I have three other cases with negative Wassermanns and symptoms of aortitis.

When you get a man from 35 to 45 with substernal oppression or even severe pain deep in the sternum and a muffled aortic second tone, or an aortic regurgitation alone without any mitral involvement you can be suspicious of syphilis. Sometimes a young case, without a history of rheumatism, with no mitral involvement and with but a slight aortic regurgitation and the other combined symptoms, even in the presence of a negative Wassermann, should make us suspicious of syphilis of the aorta and treat for that.

TRICHINOSIS IN NEW YORK STATE

Recently there have come to the attention of the Department reports of three outbreaks of trichinosis in this State; one of these occurred in Rochester, one in Yonkers, and the third in Patterson, a small village in Putnam County. The Rochester epidemic consisted of seven cases in one family, all of whom ate raw pork which had been purchased in a public market about Christmas time. In Yonkers there were ten cases, four of whom were in one family, two in another, and one case in each of four other families. It has been impossible to trace the source of the pork eaten by these people. From investigations made it seems that it had not been purchased in any one establishment; some of it had come from stores which claim to handle only western dressed carcasses; in some instances it is claimed that the pork was a present from friends, and in others that it was purchased in the form of sausage from a peddler from New York City. The Patterson cases were a mother and a 21 months' old baby who ate home-grown pork; no other cases have been found in the neigh-

borhood. Three of the Rochester cases were fatal, while none of those in Westchester County died. Laboratory confirmation having been obtained in all cases there can be no question regarding the diagnosis.

Trichinosis in the human can be prevented only by abstaining from pork which has not been thoroughly cooked; a temperature of 160 degrees F. is necessary to destroy the infecting organisms. The United States Department of Agriculture states that no system of inspection is sufficiently certain in its results to prevent the sale of pork infected with trichinosis.

Health officers and other physicians should be on the lookout for trichinosis. The physician who attended the Yonkers cases states that he is convinced that there have been many cases in Westchester County but which have been diagnosed as gripe. He points out the frequency with which edema of the eyelids occurs in this disease, which, combined with symptoms of so-called gripe, should lead one to have a blood count made at once; if trichinosis is present there will be a well-marked eosinophilia.—*New York Health News*, Vol. 1, No. 7.

THE ANATOMY AND MECHANICS OF FRACTURES OF THE FEMUR*

WALLACE H. COLE, M.D.

Miller Hospital Clinic

St. Paul

In the consideration of any fracture it is impossible to confine the discussion of the lesion merely to the bone itself as the surrounding tissues are the more important factors and are responsible for most of the complications which occur. This is especially true when taking up the anatomy and mechanics of a fracture and the problems of treatment are greatly simplified if these two subjects are thoroughly understood. The object of all treatment is, of course, to put the parts involved into their normal positions and to hold them there while healing is taking place and if one does not know the normal contour of the bone or bones involved or the various factors which tend to prevent the normal anatomy from being obtained it is impossible to intelligently handle any fracture. With fractures of the femur we must not only know the anatomy of the bone and the relation of the muscles, fasciæ, blood-vessels, and nerves to the bone and to each other but also the anatomy of the hip and knee joints and the function of these joints as related to such fractures. A knowledge of the extrinsic and intrinsic forces which cause the femur to break, which cause deformity after fracture has taken place, and which aid or hinder reduction, is also necessary. The physical properties of bone, elasticity and strength, must not be forgotten. No new facts or principles in the anatomy or mechanics of femur fractures can be given, but a brief review of what we already know will serve as an introduction to the papers on treatment which follow.

The femur is the longest and on the whole the strongest bone in the body and is a perfect example of the adaptability of shape to function in the human mechanism. The superincumbent weight of the body must be transmitted through the bone in an infinite number of positions and directions even during the ordinary daily activities of any individual and the forces applied both from the outside and by muscular action are equally numerous. We have therefore a heavy bone with a well marked forward convexity of the shaft and a strong rein-

forcement posteriorly in the form of a bony ridge, the "linea aspera," which latter adds great strength with relatively little increase in weight. The angle of the neck of the femur, which averages about 127 degrees, is necessary in order that the rotations and more complicated motions of the hip can be performed; but to prevent weakening from the angulation at this point a wonderful structural framework has been developed. The cancellous bone with which the head and neck is filled is so arranged that the supporting lamellæ are placed in the line of greatest pressure and by a truss-like arrangement distribute the forces applied through the head to the shaft of the bone. There is also a massing of bone on the under surface of the neck and a reinforcement in the body of the neck in the form of a vertical plate of bone, called by Bigelow the "true neck" of the femur and by Merkel the calcar femorale, by which latter name it is now commonly known. The greater trochanter bears no weight and is consequently very light in structure. The lower end of the femur is, like the head and neck, filled with spongy bone and the walls here become very thin in marked contrast to the thick wall of the shaft. The lamellæ of the condyles run mainly in the vertical and transverse planes.

The hip joint is a ball and socket joint which, although not as mobile as the shoulder, on account of the depth of the acetabulum, allows a remarkably free range of motion. This freedom of motion is a factor which makes possible the efficient use of traction in the treatment of fractures of the shaft of the femur and which allows the greatest liberty to patients when suspended splints are used, for no distorting force can then be transmitted through the joint to the line of fracture until after the limit of motion has been reached. In the knee joint we have almost a pure hinge motion and as long as the collateral ligaments are intact any lateral or rotatory movement of the leg must be directly transmitted to a fracture above the joint. With fractured condyles a knowledge of this stability of the knee joint is of prime importance.

The fascia lata plays an important part in fractures of the femur and a review of its anatomy is necessary if a proper understanding of the mechanical action of traction in treatment is to be understood. This structure, the deep fascia of the thigh, encircles the entire thigh and forms a complete covering for the muscles of the thigh and buttock. It is firmly attached above to the bones and ligaments

*Presented in symposium before the annual meeting of the Minnesota State Medical Association, St. Paul, October, 1923.

of the pelvis and is continuous below with the fascia of the leg but is also attached to the borders of the patella. The lateral portion of the fascia is greatly thickened and is known as the ilio-tibial band. To the upper part of this is attached the tensor fasciæ latæ and part of the gluteus maximus muscles. There are two strong bands of connective tissue connecting the femur with the fascia lata and these act as septa between the muscle bundles. One of these, the medial intermuscular septum, runs from the medial lip of the linea aspera between the adductor magnus and the vastus internus muscles; and the other, the lateral intermuscular septum, from the lateral lip between the short head of the biceps and the vastus externus muscles so that the extensor group is separated from the flexors and adductors. The importance of this great fibrous sheath with its longitudinal attachments to the femur by means of the intermuscular septa is readily seen. The muscle bundles which fill the compartments between the connective tissue septa are not only held in their proper place but the forces acting through them are guided and modified by this structure. The normal tenseness of the fascia is relaxed whenever a fracture of the femur with shortening occurs and it is then that the various degrees of deformity can take place. Traction on the extremity will tighten the fascia and this structure will then tend to mold the muscles and other structures into their normal positions. The tension on the muscles caused by traction is, of course, also an important factor but the rôle of the fascia lata cannot be minimized. If we can imagine a thigh with all the muscles removed but with the fasciæ still intact we can visualize what must take place when we have a fracture of the femur. With the tension relaxed any amount of deformity or shortening can be obtained but when traction is made on the limb this is overcome and the femur will at least approximate the normal contour on account of the action of the intermuscular septa attached to the linea aspera.

The blood-vessels and nerves of the thigh are sometimes, although rarely, injured in fractures of the femur as they occur in civil life. These injuries, when they are present, usually follow fractures in the lower third of the bone as it is here that the relation of the bone to the vessels and nerves is most intimate. The popliteal artery and vein and the internal popliteal nerve, in the order named, are the structures most likely to be involved

for they lie practically on the popliteal space of the femur and can apparently be easily torn or pressed upon by the posterior displacement of the lower fragment in supra-condylar fractures or later involved in the callus formation. The rarity of such injuries, however, seems to show that this danger has probably been over-emphasized.

The muscles of the thigh need not be taken up from a purely anatomical standpoint as the discussion of the various fractures will bring out the important points in their relation to such fractures. In the vast majority of femur fractures there must be shortening of the extremity due to the powerful pull of the muscles running from the pelvis to the tibia and also to the force exerted by the muscles having their origins or attachments on the femur itself although these latter contribute more to the deviating deformities.

All types of fracture, from simple fissures to extreme comminution, have been described in the femur. No portion of the bone escapes fracture but there are some locations which are involved more frequently than others and as a result certain typical fractures are usually described. The mechanism and anatomy of only the more important of these can be taken up at this time.

Fractures of the neck of the femur are usually caused by direct falls or blows on the greater trochanter but there are also many cases on record where more indirect forces have produced these lesions. In the aged, where we always find absorption of the calcar femorale, thinning of the cortical bone, and a fatty degeneration of the cancellous bone, very slight injuries may result in severe fractures, and falls on the knee, the forcing of the extremes of all the motions except flexion, and muscular action, although rarely, can be causative factors. If the fracture is near the head (the so-called sub-capital type), the fragments may be impacted by the driving of the denser neck into the head or be found in any degree of separation. Usually a part of the periosteum remains intact and the circulation to the head fragment is thus maintained. Impaction itself has no relation to the viability of the head as the circulation must come from the periosteum. Fractures at or near the base of the neck usually result in the firm bone of the neck being driven into the cancellous tissue of the greater trochanter and thereby frequently causing a splitting of the latter and the formation of several other secondary fractures. The trochanter may be sepa-

rated and drawn inward and the lesser trochanter may be split off with a portion of the shaft by the wedging action of the fragments. The old classification of intra- and extra-capsular fractures is one that cannot be followed, as a true extracapsular lesion of the neck is anatomically impossible and for the purposes of treatment and prognosis this division is of no importance. Most fractures of the neck of the femur show a rather typical deformity of shortening and eversion. This eversion is not only due to the action of the external rotators of the thigh and the weight of the limb but also to the fact that compression and comminution is more extensive in the posterior part of the neck on account of the more fragile bone in this location. The shortening is mainly due to the glutei, adductors, rectus femoris, and the hamstrings.

Isolated fracture of the greater trochanter is rare but can be caused either by direct blow or by muscular action. Separation of the fragment is not as a rule great, due to the tendinous fibers which so envelop it and the adjoining shaft. The lesser trochanter is fractured even more uncommonly but a few cases have been reported where the pull of the psoas and iliacus muscles in attempts to prevent a fall has separated it from the shaft.

Fractures of the shaft of the femur are usually described in three groups: those in the upper third, those near the center, and those in the lower third. Fractures in all these locations may be caused either by direct or indirect violence or, more rarely, muscular action. All types of fracture are common and the pathology depends on the nature of the force causing the break and the part of the shaft involved. In the upper third the line of fracture is typically forward and outward while in the lower third it is forward and downward. In the center the planes are transverse or slightly oblique, and if the latter, the forward and downward line is present. The normal curves of the bone seem to be important factors in causing the obliquity. Displacement and deformity is the rule in all shaft fractures unless the break is transverse without separation of the fragments, or incomplete.

With a fracture in the upper third the rule is that the proximal fragment is displaced forward and outward due to the action of the psoas and iliacus, the two lesser glutei, and the external rotators, all of which are so inserted into this fragment that their combined action tends to cause such a deformity. An important modifying factor, how-

ever, is the action of the distal fragment on the proximal one when the former is drawn upward by the powerful pull of the rectus and hamstring muscles. This pressure increases the angulation and may be strong enough to displace the upper fragment inward or backward in spite of the action of the muscles tending to cause the opposite deformity. The distal fragment in these upper third fractures is displaced as a rule upward and inward and is also everted or externally rotated. This is due principally to the action of the pectineus and the adductor group of muscles which are inserted into the medial lip of the linea aspera although, of course, the retraction is caused mainly by the rectus and the hamstring muscles as just mentioned.

There is no typical deformity in fractures near the center of the femur but in simple types the factors at work are similar to those just described. Fractures in the lower third or just above the condyles, however, show usually a displacement of the distal fragment backward on account of the action of the gastrocnemius and, to a lesser extent, the popliteus and plantaris muscles. The angulation of this fragment is rarely as marked as the diagrams in the text-books would lead us to believe and the pull of the long muscles of the thigh causing retraction and overlapping is a much more important factor. The upper or long fragment changes little in position in this fracture except that it tends toward a position of adduction and slight flexion by the action of the adductor group and the hip flexors. The sharp end of the upper fragment may penetrate the muscles on the front of the thigh and even go into the knee joint.

In all shaft fractures it must not be forgotten that the line of fracture influences the displacement to a great extent and the typical deformities and displacements just described are frequently absent on this account. The fragments tend to slide apart, when retraction takes place, along the line of the obliquity of the fracture and if this obliquity acts contrary to the usual deforming forces the latter are overcome or altered. The primary fracturing force may also be so severe that the fragments are driven into unusual positions. If a certain amount of periosteum is left connecting the fragments of a fracture this tends to hold the ends close together and although marked angulation may take place large degrees of over-riding are impossible. Gravity is also a force not to be overlooked as a deforming factor and the posterior bowing which must be

fought against constantly in the treatment of shaft fractures is largely due to this cause.

Fractures of the lower end of the femur are not so important as those of the shaft or neck from a mechanical or anatomical standpoint as the causative factors are practically always some form of direct violence and displacement when present is due to this violence. The usual lesions are fractures of one or both condyles and the intercondylar fracture. This latter may be associated with a supra-condylar fracture and be secondary to it, as the force can be so great, as in a fall from a height, that the lower end of the shaft is driven between the condyles like a wedge. A fissure with more or less separation of the fragments results.

The present absurd state of affairs cannot be allowed to continue, of waiting until a child enters school to find defects which should have been recognized and corrected years before. We therefore, as health officers, stand solidly back of any movement which will make it accepted practice to have the family physician not give up his responsibility when the baby is one year old, but have him continue his visits, at least once a year thereafter, for the recognition and correction of defects and for general advice concerning the child's welfare. If this is done, most children will enter school well nourished and without defects which handicap them in their progress and which, if corrected during the school session, involve weeks of inefficiency until there has been recovery from the operation itself and time for the benefits to develop.—*E. C. Levy, M.D., Am. Jour. Pub. Health, Dec., 1923.*

The American Medical Association is now in its seventy-seventh year. Surely there must be some reason for the continued existence of medical organization in this country. Surely it has a destiny to fulfil and I believe it will fulfil its destiny. I am not one of those that believe that the medical profession has lost the confidence and esteem of the public, the real medical profession, but I do believe that there are tendencies cropping out here and there and yonder which need to be stemmed and that it is the job of the medical organizations to initiate measures that will stem and correct them.

That is not only my opinion, that is my conviction, and I want to say, gentlemen, while it occurs to me, that we need as much as anything else in the medical profession and in medical organizations men with convictions. Everybody has opinions, few have convictions. Opinions will not get us anywhere. It takes convictions to put things over; organized medicine needs convictions. We need leaders in our county, district, state and national associations with convictions, militant men who will initiate the measures that may be needed to correct untoward tendencies upon the part of a few, those that bring reproach upon the whole profession. There is a big job for medical organization today within the profession itself.—*Dr. Olin West, Secretary A. M. A.—From M. S. M. A. Address, 1923.*

THE NON-OPERATIVE TREATMENT OF RECENT FRACTURES OF THE FEMUR*

HENRY W. MEYERDING, M.D.

Section on Orthopedic Surgery

Mayo Clinic, Rochester, Minnesota

Notable improvement in the treatment of fractures has resulted from experience gained in the World War, especially in recent compound, comminuted and infected fractures. The mortality is less and the permanent disability and period of convalescence considerably shorter. So much has been published concerning this matter that even the public has become informed of modern methods of treatment, with the result that patients, insurance and compensation adjusters, and employers are demanding better and quicker function.

The value of reconstruction surgery is recognized and appreciated; however, by a proper appreciation of conservative and non-operative methods in the care of fractures of the femur, immediate operation and the necessity for reconstruction surgery may often be avoided. Each fracture is a problem in itself; the treatment varies, and the attending surgeon is best able to judge of his ability to obtain the desired results with the means at his disposal. Methods possible in hospital practice may be impractical for the general practitioner in treating isolated patients.

CAUSES OF COMPLICATIONS FOLLOWING TREATMENT OF FRACTURES

Seventy-five per cent of cases of fracture of the femur at the Mayo Clinic present malunion, non-union, delayed union, chronic osteomyelitis, or joint stiffness following treatment elsewhere. A study of the causes of such failure demonstrates incomplete reduction and imperfect fixation or retention when first treated. Infection in compound or operative fractures often results in malunion and osteomyelitis. Improper internal fixation and inefficient postoperative retention or external fixation are not uncommon. Failure to recognize fractures of the femoral neck, and too early weight-bearing are occasional causes of non-union and coxa vara. Henderson has reported 1,000 cases of old fractures, 221 of which were of non-union of the various long bones. Of 120 cases of ununited fracture of the hip, only twenty-six were considered

*Read in symposium before the annual meeting of the Minnesota State Medical Association, Saint Paul, October 10-12, 1923.

surgical; ninety-four patients were dismissed since their condition was considered non-surgical. Henderson says, "There is no reason why, in the majority of cases, bony union cannot be obtained in the neck of the femur, if proper fixation is provided after reduction of the fracture." In 222 consecutive cases of fracture of the femur, fifty-seven were recent, the remaining 165 were mal-united or ununited, and the result of treatment elsewhere. Our experience in the Clinic, therefore, may be considered greater along the lines of complications following fractures, and reconstruction; and such an opportunity to study the cases should afford an insight into the causes of failure of treatment of recent fractures, and the means of avoiding them.

AGE AS A FACTOR IN UNION AND DEFORMITY

In the care of femoral fractures the age of the patient is of considerable importance. It is common knowledge that union occurs more rapidly and easily in youth than in old age. Fractures involving the epiphyseal line before a person is fully grown may result in mal-development and bony deformity with joint incongruity, and epiphyseal separation or fracture without displacement should be looked for. Deformity in later life, of slow development, may often be traced back to injury in youth, and radiograms will reveal damaged growth of epiphyseal ends, not uncommonly seen as genu valgum or varum, or coxa vara. Greenstick fractures are common in children, rare in adults. The patient's age sometimes determines the type of treatment; children endure recumbency, fixation, and so forth, far better than do older persons, as demonstrated by the relative infrequency of bed sores and hypostatic congestion. The average healthy adult desires freedom from apparatus and complains bitterly of the recumbency and confinement. In the growth of the shaft, nature has shown a tendency to straighten the less deformed malunions. In the aged, it is sometimes best entirely to disregard the fracture and to treat the patient, accepting deformity in order to save life.

SITE AND TYPES OF FRACTURES

The site and type of fractures demand consideration. The more common fractures of the femur may be classified into three main groups: simple, compound, and pathologic. More specifically they may be considered as transverse, spiral, comminuted or infected, extra- or intra-articular, or epiphyseal.

The usual sites of femoral fractures are: (1) the head and neck (epiphyseal separation); (2) the trochanter (trans-trochanteric, with or without separation of the lesser or greater trochanter); (3) the shaft (upper, middle and lower third), and (4) the condyle (lower shaft).

Estes has reported 584 cases of fracture, including 100 of fracture of the neck, nineteen through the trochanter, 457 of the shaft, and eight of the condyles. He found transverse types common, and spiral and longitudinal types rare.

The position of the fracture is influenced by muscular pull and the weight of the lower extremity, and a thorough knowledge of anatomy is essential if the various forms of treatment are to be applied in such a way as to insure proper results. The difficulty in standardizing treatment is obvious, if one attempts to deal with the age of the patient, and the duration, site, and types of fractures.

TREATMENT

The routine examination and treatment used at the Clinic in all cases of fracture are as follows:

A roentgenologic examination is made on admission, before the application of permanent apparatus, and after applying a temporary splint to relieve pain. A general examination is made, and the history taken, if possible, while the roentgen-ray plates are being developed. As soon as possible after ascertaining the type and location of the fracture, and assuring ourselves of the patient's general condition, anesthesia is given, and the fracture reduced. Roentgenograms are made following reduction and application of apparatus as a record, to assure ourselves and the patient that reduction has been effected. The apparatus is examined several times daily to insure proper function. Measurements are recorded from time to time, as shortening indicates bowing or slipping by of fragments. The circulation is watched, as tight-fitting apparatus interferes with rapid union, makes the patient uncomfortable, his joints stiff, and so forth. Roentgenograms are made on the fifth day, and repeated at intervals thereafter, as the judgment of the surgeon dictates, and always at the time of dismissal. The Wassermann test is made. The details of convalescence, complications, and so forth, are noted from time to time. The extremity is elevated whenever possible, thus improving circulation, preventing edema, and aiding the nurse in the care of the patient. The patient is treated on the Bradford frame and apparatus (Fig. 1),

which can be raised and lowered for the use of the bed pan, for transportation, and so forth, thus aiding the maintenance of reduction by eliminating strain. The union is tested to corroborate the roentgen-ray findings with regard to union before the patient is dismissed. Routine roentgenograms are made at right angles; often the anterior view shows apparent reduction while the side view shows malposition. Weight-bearing is permitted gradually at the beginning of the ambulatory period. An accurate record of the condition, such as length

followed by long convalescence, and not infrequently by permanent partial disability, due to stiffness of the knee, fibrous union or non-union, and shortening. We have come to regard impacted fractures with suspicion and, unless satisfied of the excellent position of the fragments, prefer to break them up, unless the patient's general condition, such as age or constitutional disease, indicates the more conservative treatment. Routine roentgenograms of injuries in the region of the hip have often led to the discovery of an impacted fracture which

of extremities, and mobility of joints, is made when the patient is dismissed from observation. With such treatment carefully carried out, the patient will secure good results, and with such records available, the physician will be protected against any future complaint.

Fracture of the head, neck, or trochanter.—Fractures of the femoral head, neck, or trochanter are

otherwise would have been overlooked, and which accounts for retarded convalescence following so-called sprains, and the later development of non-union and coxa vara. For fractures of the head and neck, the Whitman reduction and fixation method is used almost exclusively in the Clinic; it affords excellent results, and is applicable in most instances. The Ruth-Maxwell method has

also been employed; if it is, watched carefully, it is no doubt excellent. Once the Whitman cast has been applied with proper reduction, little care is required, other than prevention of pressure, sores over the sacrum, and stiffness of the knee. We apply the cast from the mid-thorax to the toes on the affected side, and to the knee of the sound leg (Fig. 2); a large window is left to permit massage of the patella, and the sacrum is well padded with

Fig. 2. (a) Cast applied, following Whitman reduction, extends from the thorax to the toes on the fractured side and to the knee on the sound side. A large window is left over the patella and the abdomen. (b) Author's method of preventing knee stiffness by means of hinges placed in the cast; later the cast is cut so as to allow knee motion.

soft felt. Care is taken to maintain the lumbar curve; in obtaining this, the back rest I devised is of value. After six or eight weeks, a pair of metal joints are placed on either side of the knee, and held by plaster until firmly fixed; enough plaster is then cut away to allow motion at the knee, thus preventing the stiffness at the joint sometimes noted. Casts are changed when the surgeon deems it necessary; usually the sound leg is allowed to remain out of the cast at the end of three months.

Abduction is maintained with internal rotation and extension until union is firm. A walking caliper is useful during the first ambulatory months, and should be so applied as to take weight off the femur and put it on the ischium. During treatment, foot drop should be prevented by keeping the foot at right angles to the tibia; if a cast is used, the heel should be well padded to prevent pressure sores, or a window should be left over it for observation. The head of the fibula also requires padding, as at this point there is danger of prolonged pressure causing peroneal nerve paralysis.

The time required for fixation is, I believe, uncertain, and must be left to the judgment of the surgeon. However, from two to four months for children, and from five to seven months for adults, may be required in order to obtain a satisfactory result. Recumbency is not necessary during the entire period. The patient should use the Thomas walking caliper splint as soon as, in the judgment of the surgeon, he is fit to walk, and union is firm.

Fractures through the trochanters respond to traction well, and with the use of the Thomas splint, excellent results are obtained. The limb should usually be placed in a position of abduction, and sufficient traction maintained to secure equal length. The degree of union, which is usually rapid, is best judged by the aid of roentgenograms. The walking caliper, fitted so as to take off weight in the ambulatory stage, is excellent. Traction is obtained by adhesive plaster, Sinclair glue, the ice tong, or the Steinman pin. I believe the ice tong to be preferable, as it allows motion of the knee and traction without pain, and does not irritate the skin (Fig. 3). Transtrochanteric fractures may lead to formidable complications unless pulled down to accurate position; malunion requires osteotomy and reapplication of traction.

Fracture of the greater trochanter or separation of its epiphysis is uncommon, and may usually be treated by fixation in abduction with a firm pad over the site of fracture. When marked displacement is apparent following fixation, open operation may be resorted to. The lesser trochanter is rarely fractured, unless as a complication of comminuted fractures, when the treatment is directed toward the injury of the shaft.

Fractures of the femoral shaft.—These are usually transverse, the upper fragment being carried forward and outward with slight external rotation. Traction in the axis of the upper fragment is usual.

ly sufficient to overcome shortening, and will reduce the fracture unless interposition of muscle has occurred. It is better to reduce the fracture and apply the apparatus under anesthesia, as this gives the surgeon an opportunity to manipulate thoroughly, to stretch muscles, and to apply traction painlessly. Temporary traction to prevent shock

Fig. 4. Thomas extension splint.

or further damage to soft tissues is indicated during transportation. The Thomas splint should be carried in all ambulances and be available in hospitals for emergency purposes. The temporary traction is readily applied in emergency practice with the Thomas extension splint (Fig. 4). Such care lowered the mortality in cases of compound comminuted fractures during the war, and saved thousands of useful limbs. There is no question as to the value of the Thomas splint in emergency fractures, especially the compound comminuted; it has supplanted lateral splints, plaster-of-Paris, box splints, and so forth, in most of the clinics in this country. The surgeon in private practice has sometimes found the extension traction treatment extremely difficult, as constant care and supervision are required to maintain reduction and prevent relatives and friends from interfering with apparatus. Even in hospital practice, team work is required in order to secure and maintain reduction, and, as a result, special clinics for the treatment of fractures have been formed in various institutions with an especially trained personnel. Such grouping will no doubt result in a more or less standardized treatment in hospitals, and in the better care of the patient.

Simple traction or manipulation may not properly reduce the fracture. I have observed equal length with muscle between the fragments, and, in spite of careful manipulation, found it necessary to operate when it could be demonstrated that muscle and periosteum were interposed. Muscle is not always removed from between the fragments with traction. Further, muscle intervention delays union and may produce malunion or non-union. Kidner and Lakoff have reported six cases of muscle interposition, and believe that crushing and twisting are the principal causes. We operate for open reduction when, after reasonable effort, the roentgen rays show unsatisfactory position, and the time since fracture has been short. Such operations should be performed before organization of the clot or callous formation.

Fig. 3. (a) Ice tongs traction applied. Anterior view. (b) Lateral view showing ice tong slightly anterior to the axis of the femur, so as to pull the upper end of the lower fragment anteriorly. (c) Result of force applied in fracture of lower shaft of femur.

Although the Thomas splint has, to a large extent, supplanted the lateral splint, plaster-of-Paris, and Buck's extension, we nevertheless continue to use them occasionally. In children, fractures of the shaft are successfully treated by the Bryant suspension, as has been shown by Burdick and Siris. Fixation in plaster after reduction was formerly considered an excellent method, and will continue to be used by many. Care should be taken whenever windows are left in casts for observation of wounds, that bowing or rotation does not take place.

should be avoided. We have used an oblong block of $\frac{3}{8}$ -inch wood, wide enough to keep the adhesive off the malleoli, and prefer two or three thicknesses of adhesive and a carefully applied boot of adhesive, open in front, rather than two or three strips applied about the leg. We use Buck's extension frequently. We have also used Sinclair's glue and find it excellent in its adhesive qualities, but, like paint, it is messy and slow. Ice-tong traction, combined with the Thomas splint, is no doubt most efficient, and less apt to carry infection into the cancellous bone than the Steinman pin. The Wil-

Fig. 5 (Case 1). (a) Fracture of the neck of the femur. (b) After reduction, showing anatomic reposition. In (b) the roentgenogram was taken through plaster-of-Paris cast.

Traction may be obtained by means of adhesive plaster or moleskin, Sinclair glue, plaster cast, Hodgen's splint and pressure against the calf, ice tongs, Steinman pin, or the Finochetto stirrup. In most instances skin traction may well be extended beyond the site of fracture, as skin is elastic and gives readily; this is especially true when anesthesia is given, and reduction and traction made before the extension apparatus is applied. The skin should be prepared by shaving and washing to remove hair and grease, and the adhesive changed occasionally to prevent irritation.

Care should be taken when adhesive extends over the peroneal nerve, and pressure over the malleoli

cox universal splint deserves consideration, as it is applicable to the arm as well as to the leg. A properly fitted ring will, however, be found of greater comfort. As I have already stated, we have had difficulty in obtaining reduction by traction alone, and prefer anesthesia and manipulation, using the traction to maintain reduction. The amount of traction may be reduced after a few days; otherwise, overlength may result. In spiral fractures, even after equal length has been obtained, the bone often remains separated one-half to three-fourths of an inch. Further traction may even lengthen the leg without coaptation. When flannel supports or aluminum strips beneath the

fracture site fail, we apply a sliding ring to the splint and, by means of plates screwed against the thigh, force the fragments from any angle into position. Flannel bands may similarly be applied and run over a pulley with weights sufficient to cause correction. When applying the Sinclair modification of the Thomas splint, care should be taken to support the knee properly, to keep the foot and ankles at right angles, and to have the joint of the splint directly over the middle of the knee joint. One of the principal difficulties in the care of fractures of the shaft is backward bowing, and sufficient support behind the site of fracture, either by flannel bands, aluminum bands, or overhead traction, is essential.

Fractures of the lower shaft and condyles.—In fractures of the lower shaft and condyles, the upper end of the lower fragment is practically always displaced backward, the sharp edge of the fracture resting on the nerves and blood vessels. Anesthesia is essential in reduction, to relieve muscle spasm. Pressure is to be avoided over the fractured ends, lest more injury to soft parts be produced. Gradual traction, with the knee partly flexed, and the assistant bearing down on the shaft above the fracture while the surgeon forces upward with his hand under the condyles, will usually accomplish reduction. Certain spiral or slanting fractures may force the lower fragment upward and to the side; in such cases, traction is essential, with knee flexion. However, should difficulty be encountered, and reduction be unsuccessful, open operation is indicated. Reduction is perhaps best maintained by the use of a double inclined plane, either as half cast, wooden wedge, modified Hodgen splint, or Sinclair modification of Thomas splint; the latter is perhaps the best. The great advantage in using the ice tongs or Steinman pin in fractures in the lower femur lies in the avoidance of stiffness in the knee. Charbonnier has obtained satisfactory reduction with the Steinman pin in 85 per cent of his cases, with no serious after results, union taking place in from twenty-five to fifty days, and Dennis Crile reports 300 cases reduced without difficulty. The insertion of these appliances in fractures of the lower shaft should be anterior to the middle axis of the femur, so as to pull the upper end of the lower fragment forward.

Anterior displacement of the lower epiphysis.—Reduction in these cases is difficult, and should not be attempted without anesthesia. After the patient

is thoroughly relaxed, traction is made with the knee slightly flexed by the assistant, while the surgeon grasps the leg with both hands just above the epiphyseal line, and with thumbs on either side forces the epiphysis downward over the end of the femur. The leg is then put up in right angle flexion and maintained in this position for several weeks, after which gentle motion is begun. Should it be impossible to manipulate the epiphysis into position, I have no hesitation in opening through a lateral incision to reduce the fracture, and I secure fixation in anatomical reposition by means of beef-bone screws.

Intra-articular fractures.—Unless intra-articular fractures are perfectly reduced, they lead to permanent partial disability, and therefore the use of conservative splints, casts, and so forth is, we believe, fast losing ground in favor of open reduction and internal fixation.

Compound fractures.—Our method of caring for compound fractures may be summarized as follows:

With a sterile gauze pack, saturated in Dakin's solution or iodine, over the wound, the surrounding skin is shaved and cleansed. The protruding bone and tissue is thoroughly washed with a large quantity of Dakin's or a solution of iodine. The soiled tissue and small fragments of bone are excised.

Fig. 6 (Case 2). Result eleven months after fracture of the hip. Good function.

The fracture is then immediately reduced, under anesthesia, and suitable apparatus applied. If the wound has been extensively soiled and the surgeon does not believe he obtained a clean wound by the foregoing measures, the wound is Dakinized and

packed for forty-eight hours. The wound is then allowed to close of itself, or is loosely sutured and left alone. Fifteen hundred units of anti-tetanic serum is given. Intra-articular wounds are not Dakinized. Iodin may be used instead of Dakin's solution to cleanse or wash the wound before and after débridement.

REPORT OF CASES

Case 1. Mrs. C. A., aged seventy years, fell on an icy sidewalk in February, 1922, fracturing the right hip. The characteristic eversion, shortening, and so forth, were present. A roentgen-ray revealed fracture of the neck with upward displacement.

The patient was anesthetized and Whitman manipulation performed; a cast was applied extending to the knee on the sound side and to the toes on the fractured side. Windows were left over the abdomen and patella. Part of the cast around the knee was removed, side hinges were inserted, and knee motion begun at the end of eight weeks. The patient, being old and feeble, was permitted to be moved about in a wheel chair. At the end of the third month of treatment, all apparatus was discarded because of the patient's general health; the legs were of equal length, and as union was apparently firm, she was encouraged to walk with crutches. At the end of six months, she was dismissed as cured, walking.

Comment.—Treatment was abandoned at the end of the third month, yet a perfect result was obtained in six months. This case illustrates the occasional necessity of treating the patient first and the fracture second (Fig. 5).

Case 2. Mrs. M. C., aged fifty-one years, fell and injured her left hip January 19, 1921. A roentgen ray revealed fracture of the neck of the femur. There was eversion and three-fourths of an inch shortening. Extension with internal rotation was applied until abdominal distention, nausea, leukocytosis and complicating symptoms cleared up. January 28 the fracture was reduced by the Whitman method, and a cast applied. The cast was changed April 27 and May 18. September 21 union was firm and the patient was walking with a cane. She has made excellent recovery with one-half inch shortening.

Comment.—The patient sustained several falls during convalescence, following which knee motion was improved. A cast was not applied and the patient was not subjected to anesthesia until I was convinced that her general condition was satisfactory. The roentgen-ray shows the result after eleven months (Fig. 6).

Case 3. A plasterer, aged forty years, fell eight feet, and struck on his right hip. He was brought into the hospital at once. Examination showed outward rotation of the right leg without shortening, pain in the hip, and inability to raise the leg from the bed. Roentgenograms revealed an impacted fracture in excellent position. With equal length and excellent position, there seemed to be no indication for breaking up the impaction. Treatment consisted of traction with a Thomas splint.

The patient left the hospital the second week, to continue treatment at home. He was observed from time to time,

and roentgenograms were made. At the end of nine weeks he was up and about, walking on crutches with the aid of a caliper splint. At the end of one year, union was perfect, and the position correct, with equal length, good motion in the joint, and no atrophy.

Comment.—This case is cited to show that, although the Whitman method is a practical standard, and we are suspicious of every impacted fracture of the hip joint, many of which require manipulation, yet there are exceptions to the rule. The ultimate result is shown in Figure 7.

Fig. 7 (Case 3). Roentgenogram showing impacted fracture of neck of femur.

Case 4. A boy, aged six years, fell off a wagon into the spokes of a wheel. A roentgenogram, anterior view only, was taken by his physician, and no fracture found. A splint was applied for two weeks, and the patient then advised to walk.

At examination, during the fifth week, the left knee was swollen and tender, with anterior displacement of the epiphysis. The malunion was broken up through a lateral incision and the epiphyseal separation reduced. Within six months 90 degrees motion resulted.

Comment.—This case illustrates the advisability of always taking anterior and lateral roentgenograms (Fig. 8).

Case 5. A farmer, aged forty-two years, was brought about fifty miles by automobile to the Clinic by his family physician. He had sustained compound comminuted fractures of the left tibia and fibula with dislocation of the ankle joint and multiple lacerations of the legs. The right femur was fractured at the juncture of the lower and middle thirds. The accident occurred in the morning, and he arrived at the Clinic in the evening, dressings and splints having already been applied.

Roentgenograms were taken immediately, anti-tetanic serum was given, and the patient was prepared for operation on the left leg. Through two lateral incisions, the fractures of the tibia and fibula, and the dislocation were reduced, and held by a nail and Parham-Martin band; the

Fig. 8 (Case 4). (a) Lateral view showing lower epiphyseal separation of femur. (b) Result, one year after reduction. Note anterior bowing of femur as a result of damage to epiphysis.

fractured femur was placed in a plaster-of-Paris cast with the knee slightly flexed. Eight pounds of extension was applied to the suspended right leg through the cast. There was no infection. A month later a Sinclair modification of the Thomas splint was applied and active knee motion begun, and continued until the seventh week. The patient then returned home with the cast split into anterior and posterior halves, having been advised to remain off his feet.

The patient returned seven weeks later, having walked on both legs. The right femur remained firmly united in spite of bearing most of his weight. The left tibia bowed out-

ward. The patient was operated on and the Parham band and nail were removed. The tibia and fibula were manipulated into position and a cast was applied. The patient went home the fourth week under the home physician's observation.

Comment.—Surgery of the left leg was indicated, and amputation was considered. However, infection did not result in spite of the crushing and soiled comminuted fractures with dislocation. Conservative treatment of the left femur resulted in early function and good knee motion (Fig. 9).

Fig. 9 (Case 5). Result of conservative, non-operative treatment of fracture in lower third of femur. Anterior and lateral views.

SUMMARY AND CONCLUSIONS

In the conservative treatment of fractures of the femur, after the patient's general condition has been considered, and roentgenograms taken, immediate reduction should be undertaken, and anatomic reposition obtained, if possible, and maintained by suitable apparatus, to prevent stiffness of joints, useless atrophy, pressure sores, and so forth. To correct deformity properly, and maintain reduction, the anatomy must always be carefully considered. Anatomic reposition is, of course, the desired end, but good function may be obtained without perfect reduction. The patient's temporary comfort should not be allowed to interfere with the ultimate result, for although the force required to overcome muscle pull in adults often makes traction uncomfortable, inefficient traction and comfort lead to improper reduction and failure.

There is no rule as to when union will occur, but the roentgen ray and clinical findings are helpful guides. Anterior and lateral roentgenograms, before and immediately after reduction, are advisable. Further roentgenograms may be taken at the discretion of the surgeon, but should always be taken at the time of dismissal. The history should be continued throughout treatment, and a careful record of measurements kept.

In cases of fracture below the femoral neck, traction by means of the Thomas splint or its modifications (Fig. 10), such as Sinclair's, is the most efficient conservative treatment. The amount of traction will, of course, vary with the patient. The means of obtaining traction may be skeletal or from the skin; the former is the more efficient. The use of the Thomas traction splint in emergency treatment is of unquestionable value.

Compound fracture should receive immediate cleansing and débridement, and antitetanic serum should be administered to the patient.

Physiotherapy is a valuable aid in the treatment, and in uncomplicated cases, and with the use of a caliper splint or Steinman pin, may be carried on throughout convalescence. If the Thomas splint is used, the skin near the ring should be massaged daily, and soothed with alcohol or talcum. Considerably less atrophy results if daily massage is employed, and as a result of the improved circulation, the time required to obtain firm union is often shortened. The physiotherapist may also help to prevent pressure sores by massaging over the sacrum, even in the presence of a cast. Motion

of joints and gentle massage under supervision also obviate stiffness; this is especially true in cases of old arthritis.

Conservative treatment is more adaptable to children than to adults, for in children slight deformities tend to correct themselves, and joint complaints are rare. However, epiphyseal separation and injury are more common, and may lead to subsequent deformity. Adults require more protracted care than children, and are more difficult to confine. There is less tendency to correction of deformity following union, and greater tendency to static joint complaints. Open operation is, therefore, more often resorted to, except in fractures of the hip, in which treatment by Whitman's method usually gives accurate reduction and retention. In most cases, when a reasonable attempt at conservative treatment fails to provide satisfactory reduction within five or seven days, open reduction is advisable if suitable operating facilities are available.

Fig. 10. Modified Thomas splint to allow knee motion.

Our experience at the Clinic has led to the following conclusions:

1. The Whitman treatment of recent fractures of the head and neck is efficient, and open operation is unnecessary.
2. In the recent fractures of the shaft, the non-operative treatment has apparently given more satisfactory results, although a comparison of these cases with those in which operation was performed is unjust, since open reduction was performed in only the more difficult cases. Anesthesia, manipulation and retention by extension with Thomas splints, has been the method of choice in simple fractures. In twenty-seven of twenty-nine simple fractures treated conservatively, the results were satisfactory.
3. Excellent results are obtained in supracondylar or condylar fractures in the lower shaft, by

flexion of the knee and extension. When the Steinman pin or ice tongs are used, they should be accurately placed anterior to the axis of the femur.

4. Unless practically anatomic reposition is obtained in the intra-articular fractures by conservative treatment, arthrotomy and internal fixation is indicated.

5. When, after reasonable attempts, conservative treatment has failed to give satisfactory reduction, open operation, reduction, and fixation is advisable.

THE OPERATIVE TREATMENT OF FRACTURES OF THE FEMUR*

CHARLES A. REED, B.S., M.D., F.A.C.S.

Associate Professor in Orthopedic Surgery

University of Minnesota, Minneapolis

If the results obtained in femoral fractures were entirely satisfactory there would not be much point to this symposium. Speed, Eliason, Carroll, Kidner and others have recently published reports of the results obtained in the larger clinics that are worthy of careful study. Eliason describes the routine treatment in the University of Pennsylvania Hospital, which consists of first applying extension and placing the fragments in as good position as possible without the aid of an anesthetic. They are left in this position about three days and then radiographed. In eighty-eight cases so treated, all were found to be in bad position when radiographed. Yet it will be admitted that this simple extension treatment of fractures of the femoral shaft has been depended upon until recently to replace the fragments in their proper position and hold them there. It has been assumed that if a surgeon applied a Buck's extension of say twenty pounds he could not be blamed for any bad result that might accidentally occur. Statistics show a percentage of permanent disability in these fractures, even in the best hospital practice, that ought to fill us with discontent. The bad results are not found in the closed cases alone. Open methods have their full share. Indeed, there has been a reaction against the epidemic of open operations of a few years ago, particularly against the indiscriminate use of the steel plate.

The profession is awaking to the fact that the treatment of fractures has not made the advances of other branches of surgery. One of the reasons for this may be the lack of specialization in this field. Usually the nearest doctor is called and few cases are referred. In the case of thigh fractures, transportation was not only painful but positively dangerous until the Thomas splint came into general use. As a result of everybody treating these cases, few surgeons see enough of any one type to work out comparative results and add much to our scientific knowledge. The current literature on fractures is overwhelming. Differences of opinion are greater than in any other branch of surgery.

*Presented in symposium before the annual meeting of the Minnesota State Medical Association, Saint Paul, October, 1923.

The equipment proposed would fill an instrument shop. The crying need is for simplification of both method and equipment. Until some of the methods have been perfected and others proved inadequate and discarded, standardization can hardly be hoped for. Still the aim of this paper is to offer some suggestions along this line.

The indications for operative treatment are sometimes difficult and at other times obvious. Examples of the latter are compound fractures, true cases of non-union and cases in which there is interposition of soft parts. Open replacement alone offers hopes of a good result in these cases. In oblique fractures traction can almost always be depended upon to give at least a fair result provided the soft parts are not interposed. It is in the case of transverse fracture that decision is most difficult. If repeated manipulations under an anesthetic have been tried and the limb put up in traction with the distal fragment in line with the proximal fragment, still shows displacement, shall an attempt at open operation be tried?

A committee appointed by the British Medical Society to report on the ultimate results obtained in the treatment of simple fractures, with and without operation, presented some interesting conclusions. They are too long to quote in full, but in brief they found the results in children good by the closed method but poor in the case of adults. They stated that "although the functional result may be good with an indifferent anatomical one, the most certain way to obtain a good functional result is to secure a good anatomic one."

In deciding upon operation other factors than the fracture itself must be considered. Of these the age and health of the patient and the skill and equipment of the surgeon are most important. Under equipment are included not only suitable bone instruments but a good hospital, trained assistants, a bedside x-ray outfit and a traction operating table. If operation is indicated so far as all these factors are concerned, the problem must then be put up to the patient himself. He must be made aware of the dangers of the operation while at the same time the probable interference with function and greater possibility of non-union if not operated must be pointed out. It must not be overlooked that repeated manipulations may do more damage to the tissues than open operation.

Due to our war experience many cases can now be handled by the closed method that formerly

would have required open operation. Still we must not expect to exactly copy the results obtained in gunshot wounds. General Bowlby, of the British Army, has called attention to the much greater difficulty in getting full extension in civil fractures than in the lacerated thighs seen in the base hospitals. At the same time bone surgery has made great advances and the dangers of operation have been reduced. Better function is now expected and certain cases must be operated that were formerly allowed to unite in a faulty position.

The multiplicity of methods and appliances for holding the ends in apposition is proof in itself that no one method is entirely satisfactory although many are ingenious and produce good results in the hands of the originators. Only the simplest and most used methods will be mentioned. Some of these attempt not only to hold the ends in apposition but at the same time to actually splint, that is, to prevent angulation by internal means. The steel plate does this most efficiently from a mechanical standpoint and is about the simplest internal splint to introduce. Unfortunately the steel plate has the serious defect of causing irritation and interfering with union. Infections are frequent and the plate must often be removed. The beef bone plate with the threaded beef bone screw is somewhat more difficult of application, more bulky and not as strong but is much less irritating and in most cases is eventually absorbed. The autogenous inlay graft is still less efficient mechanically but has the great advantage that it is non-irritating and is actually stimulating to bone repair. In the case of ununited fractures it is often indispensable. It is usually not a justifiable procedure in a fresh thigh fracture because of its difficulty of application and the extensive dissection required in a thigh to expose a sufficient field through a thick mass of muscles. Unless a sliding graft is used it also necessitates a second incision to remove the graft from the tibia. It has been found that it is not safe to depend upon the splinting effect even of the long steel plate as the powerful thigh muscles will finally produce angulation with loosening of the screws.

The principal methods of end to end approximation are by the short bone or ivory plate, the intermedullary graft and suture. The Magnuson ivory plate method is very efficient mechanically. It consists of a thin ivory plate which is fitted into a keyway cut edgewise in the ends of the bones. It is held in place by special threaded ivory bolts

screwed in at right angles to the plate through the entire shaft. The method requires special plates and instruments. The intramedullary graft is simple but is physiologically wrong as the periosteum and endosteum must be removed from the graft and the medullary cavity cleaned out at the very point where it should be preserved. Also it is difficult after the graft has been introduced into one end to separate the fragments enough so it can be introduced into the other. This has been accomplished in various ways. The graft has been introduced full length into one end and the fracture reduced. The ends are then pried apart enough so that the graft can be teased back into the other. Another method is the so-called "submarine" graft. A short graft is cut similar to the familiar sliding inlay graft but the incision is not carried down within an inch of the end of the fragment. This is sunk into the medullary cavity and driven endwise into the other fragment. The intermedullary graft has many advocates in fresh fractures and is a method that must be seriously considered because of its simplicity and efficiency.

The mechanical efficiency of simple suture depends to a large extent on the material used and the method employed. Wire is not only a foreign body which is irritating but is difficult to fasten and is apt to kink and break. Soldering the joint, which has recently been suggested, would not help. Of all materials proposed to date, Kangaroo tendon seems to come nearest to meeting the demands. It is remarkably tough and but slightly irritating and, while it is absorbable, it lasts until bone union begins.

Having decided in a given case that open operation is necessary, proceed to get the fragments in place and hold them there in the simplest method possible and yet with a well worked out plan and ready for any contingency. As a rule traction straps should be applied from knee to ankle before operation. The entire thigh should be scrubbed up the day previously and an alcohol pack applied. The operation should be performed on a traction table of the Hawley type. The proper draping of the patient is of great importance in carrying out a clean technique. The leg must be draped so that the various manipulations do not expose unsterile fields. For this purpose the leg below the knee should be wrapped in snug fitting drapes held in place with a sterile bandage and then placed above the sterile sheet. Jones wraps the operative field in

sterile muslin and makes the incision through this. The incision in a shaft fracture will usually be on the outer anterior aspect. Start with a short incision in a transverse fracture as this may be all that is necessary. When the ends are reached remove clots and attempt to pry the fragments into position. In many cases the ends can be locked together and the limb put up without any internal fixation. If they tend to slip they must be fastened. Kangaroo tendon will hold in most cases, if properly applied. The much used method of drilling through the entire shaft from side to side, perhaps an inch from the ends and passing a single strand of wire or other suture through these holes is absolutely futile. The sutures must be introduced so as to prevent lateral movement. After the ends are in good apposition drill holes in pairs close to the fracture line and extending through the cortex only. There should be two pairs of holes placed at least 90 degrees apart on the circumference. When these holes are drilled, relax the extension and allow the ends to angulate out into the wound. It is usually difficult to lace the kangaroo tendon through these holes with a stiff needle. An improvised suture carrier made of a loop of piano wire (heavy tonsil snare wire) firmly set in a hemostat greatly expedites this step. This carrier can be bent into any desired shape and easily slipped through the sharp walled holes either from within or without and the tendon threaded into it and pulled through. Long strands should be used and these should be laced through two or three times. This is important as twice through more than doubles the strength since the knot is the weakest point of any ligature. Once more bring the ends into apposition and draw the sutures just snug and tie. Experiments by the writer have shown the efficiency of sutures so applied. A transverse fracture fastened with three strands of heavy tendon withstood an angulating strain of over twenty pounds applied six inches from the fracture.

Opinions differ as to temporary drainage. Eliason reports that all cases of nonunion or delayed union occurred in his undrained cases. Others have had similar experiences and most operators put in a few strands of silkworm gut.

The strength of simple suture properly applied has been underestimated. If the operator does not feel that it is strong enough in any particular case, it would be best to resort to the steel plate for the transverse fracture and the Parham band for the

nately, for some reason or other, angulation has occurred, then I think it can be corrected.

Now this man here is a big, strong, muscular fellow. I have him here and I will have him walk in so you can see what his result is. This result will be what you see here anatomically, and the functional result will be what you see when you see him walk across the room. This man was not treated by me at first. For the last three or four years the resident at the hospital has been treating fractures of the femur, and he treated them under a good deal of difficulty, and he did very well, as you will see from some of these results. But every once in a while I would be called upon to see a man and I would find that his measurements were not very good; and I thought he was not going to have a good result, and then we would do something else. This is the position after he had been treated for three or four weeks. He was given an anesthetic and this position corrected some, as you see, pulled down a good deal more, and a good deal of weight put on; and this is the result.

Now it is a bad looking mess. Very early in the x-ray work I was associated with the late Dr. Wheaton, and I used to enthusiastically show him some x-ray pictures of fractures, and he would say, "Throw out your old x-ray pictures and show me the patient. I want to see the patient." So on two or three occasions where I was inclined to get anatomical perfection he would say, "That is good enough. You have a straight limb." I tried to correct it two or three times with his sanction, and I never improved it very much; but the patient got a good result. Later on, I might say, he became convinced of the value of x-ray pictures and said, "I don't see how I ever practiced surgery without them."

Just as in gross and histological pathology, we come to have a combined experience of clinical and radiographic evidence; and if we do not use both of those evidences, the clinical and the radiographic together, and take the sum of the result, we are going to get into trouble.

I might say—with whatever criticism it may bring—that I have never operated on a fracture of the femur. I have operated on some other fractures where the indications were quite apparent; but I have not operated on a fracture of the femur; and there is only one that I can think of where I wish I had.

This man here had a fracture of both femurs. He was a very obstreperous, sensitive fellow, and we had a great deal of difficulty in treating him. Now just as in that man in the picture I showed before, so in this man at the end of two or three weeks I anesthetized him, pulled it down and improved the position; and this slide shows what we finally got. We did not have any way of checking up the measurements because both were fractured. There is a difference of a little less than a centimeter between the two femurs, and he walks without any limp and perfectly well.

This woman was treated by the resident doctor, and I saw her repeatedly with him and was very much interested in the case. These are pictures taken at various times, showing the position of the fracture, and these are the final results. There is nothing more to say about that except that she was treated in this same traction. We will

have her walk in. (Woman walks across the stage.) This woman has been out of the hospital some four or five months. The first man has been out about six or eight months.

This is rather a remarkable series of pictures. That boy came in with a diagnosis of fracture of the femur, and there was something at once that was peculiar about it; I mean he gave a history of having had some disability and they thought his leg was broken before; and now he had broken it over again. So we took these pictures. This was the first picture. Now, of course, this shadow here and the rather porous condition of the bone and this sort of indefinite shadow out here attracted our attention at once, and we wondered. We put him on the same kind of traction that we have here, and this is the picture a little later, showing a great big arc of bone showing out here on each side, with the shaft of the femur in the center. This is a later picture, showing this bone having increased in density, and this shaft here acting as if it some time might be a sequestrum. In other words, the boy had a chronic osteomyelitis that he had been walking around with and paying no attention to until he fell and broke it, and then they put him to bed for a week or ten days; and as soon as the soreness got out of his leg he got up and walked around and broke it again; and this is the result here.

The interesting thing about this boy further was that after he had been in the hospital under treatment for about a month with traction, he suddenly developed a swollen elbow and had a good deal of pain and a good deal of fever. I will have the boy walk across the room so you can see him. (Boy walks across the stage.) He has been out of the hospital now for two or three months, and he is walking on that kind of femur; that is, he has osteomyelitis. He hadn't any elevation of temperature until the complication of the elbow arose. After this elevation of temperature and swollen elbow had existed for a week or so, I decided that he had an osteomyelitis at the lower end of the humerus, and simply incised the abscess down to the bone and drained it.

The extraordinary thing about this femur is that he has osteomyelitis. He has had it for many months. He had a fracture and it has united; there has been enough plastic material thrown out. You see it has never discharged; it hasn't any opening. The bone is not very tender; his thigh is perfectly straight. You can see that osteomyelitis at the lower end of the humerus with simple drainage, without any attack on the bone at all, has been cured. This young bone has acted very much like soft parts and has drained itself, and the elbow is apparently perfect. The bone, of course, is the most prolific tissue in the body. I think the osteoblasts do more for repair than any of the other tissues we have. The repair of children's fractures is unusually rapid. The amount of new bone thrown out—it is thrown out very quickly—the bone, by virtue of the static demands and the growing under those static demands, acquires its shape, even if there is primary deformity. If there is not too much angulation they will in time correct that, not only in the femur and tibia, but in the arm bones as well. I have watched them for years—some of them where there was a very great deal of displacement—and they are corrected.

It seems to me that these pictures show pretty positively that operative treatment in fractures of the femur is rarely called for. That first man was a great big strong fellow, and so was the man in the pictures of the second case you saw that were treated by this simple method of traction. The traction is continuous, and the limb is in such a position that you can inspect it at any time you want to. It must be measured frequently. If that is done I have come to think that fracture of the femur, in the shaft at least—and Dr. Meyerding and Dr. Cole and Dr. Reed have all emphasized the value of the abduction treatment in fractures of the neck—I think it is pretty unanimously agreed that this is the treatment for most cases. It seems to me that the cases that have to be operated on are very rare, indeed.

Now, just one minute about the hospitalization. This very valuable article of Dr. Speed's to which I referred, says that fractures of the femur are all subject to hospitalization and they should be treated in the hospital and they should be treated by radiography control. Well, that is very fine, and it is the most desirable thing to do. I feel that the radiograph in its connection with fractures is one of the most valuable things we have in the sense of studying fractures, just as the microscope is a very valuable thing to study tumors. After you have studied them for a long time, you get to know them. So with the study of fractures with the radiograph. The combined radiograph and clinical study—and the clinical study must not let up one minute during the time that you are interested in the radiograph, because if you do you will get into trouble. But with that combined study it is fine.

I believe, however, that in most fractures of the femur, and I think it should be recognized as true, because a very large number of fractures have to be treated in the country; they are not near a hospital, it is difficult to move them—I think they can be treated perfectly well if they are treated with the very simple arrangements which we use with the Thomas splint, which makes it impossible for the traction to let up, and if instead of using the radiographic control you will use the clinical control to watch your apparatus and make the measurements every few days, I think you are bound to get a pretty good result.

DR. A. E. WILCOX, Minneapolis: These very interesting papers heard this morning emphasize the importance of, and are evidence that, we are beginning to appreciate that the treatment of fractures is a difficult department of surgery.

While I was listening to Dr. Colvin, I was reminded of a case which we are now observing. The patient is suffering from a fracture of both thighs, simple in type, and, although she is in a hospital where available equipment is efficient, in fact, apparatus which I am particularly partial to and think I know how to apply, we are having a great many difficulties. We are experiencing a problem, the solving of which necessitates the management of a delirious patient, resulting from fracture of the skull, complicating the fractured thighs. We are having local abscess from broken down hematomas of the soft structures, and all the while we are trying to keep proper extension on the thighs by caliper skeletal traction. It is not difficult to visualize the problem, or to appreciate the problem.

In the treatment of fractures there are three fundamental

principles which have been emphasized in all the papers read today. They are: First, selection of the type of treatment, according to the type of case, age of patient, etc.; second, the general principle of extension and counter extension, and third, forms and methods of mechanical apparatus for holding reduced fragments in place after reduction has been attained. By keeping these fundamental principles in mind we stand a good chance of obtaining the result desired, namely, a good functional result, and if not an entirely satisfactory result an anatomical one.

The subject of the treatment of fractures of the thigh could be discussed indefinitely. I, therefore, prefer at this time to adhere to a discussion of the three fundamental principles mentioned.

In the General Hospital, Minneapolis, upon admission of a fracture case, we attempt to classify same, operative or non-operative. We consider skeletal traction, in any form, operative, and so classify such cases for the reason that the procedure must be carried out under the same conditions and with the same technique as that exhibited in more formal procedures. After classification, and the treatment selected, the next thought is extension and counter-extension. In fact, extension is thought from the time the patient is seen by our house-officers at the scene of accident, at which time, in cases of fracture of the thigh, a Thomas splint, which is carried in the ambulance, is at once applied and the patient reaches the hospital with the leg under the influence of extension.

Following application of more refined extension and counter-extension with our standardized splints we come to an important part of the treatment. We may be very much satisfied with our efforts up to this time. Reduction is good, patient comfortable and apparatus well applied, but from this time on the importance of daily observation and adjustment of the apparatus cannot be overestimated. Calipers must be watched, the wounds kept clean, supportive toweling smooth and on the right tension, and the position of the fragments checked and rechecked repeatedly with portable x-rays.

One must have the intelligent co-operation of the house staff and considerable enthusiasm amongst the associates. In fact, the concerted effort of every one coming in contact with such cases is necessary to obtain the best results. Without this co-operation, unless one has the time to do all adjustment themselves, you are going to find, sooner or later, that deformity has occurred, just as Dr. Colvin has stated, which may require repeated anesthesia and correction. Therefore, I think the post-traumatic period, after classification, reduction and fixation, is a very important period as regards treatment. Observation during this period must be most conscientious, diligent and continuous, for even where there is internal fixation by steel plate application, the strong muscles are everlastingly contracting and produce secondary deformity unless continuous extension is applied long enough to attain callus formation.

Another point in all fractures of the thigh is the question of when to allow weight bearing. Assuming good alignment, good callus formation and functional joints, weight bearing must be deferred until the callus is hard. It is our custom to urge these cases to use caliper walking splints, depending upon their weight, activity and amount

of callus, for three to six months after union has occurred. I am particular to see that the patients co-operate with these suggestions and use the splint continually. Under these conditions children may soon return to school, or adults return to certain types of employment without danger of secondary deformity or bowing. One such secondary deformity in a limb which was not protected, although in perfect condition when discharged, was sufficient to teach me this lesson.

The question of treatment of thigh fracture is very important, as Dr. Meyerding says, for the responsibility of the surgeon in these cases is very great. He is responsible not only for good functional results, but patients expect good anatomical results as well.

I do not quite agree with Dr. Colvin when he states that all cases of fracture of the thigh can be treated satisfactorily by extension alone. I have a number of cases in which I am fully convinced I have obtained much better results by operating upon them than I would have had by using extension only in the treatment, and at the present time, from these experiences, I am satisfied that operation in selected cases at times is clearly indicated.

Another thing—our responsibility in court is such that the presentation of some of the x-rays such as Dr. Colvin has shown this morning, if exhibited by a less famous surgeon, would be apt to bring from a jury, even where the functional result has been so good, a large verdict. A famous man can get away with such types of cases by emphasizing the importance of functional results, but the jury, where they are allowed to view x-rays of this type, would certainly be doubtful about the efficiency of the treatment. Until we educate the people to the fact that functional results are the thing to be obtained and that frequently it is impossible to secure good anatomical alignment, as shown in x-rays, we are going to run the chances of having verdicts against us in the courts.

DR. E. K. GREEN, Minneapolis: I want to emphasize one or two points which were brought out. Dr. Wilcox, I think, has made one of the most important points here this morning and that is in regard to our being everlastingly on the job. These cases are not easy; they are major cases, and it is very necessary that they should be looked after continuously.

There is one point with regard to the matter of extension which I would like to bring out here, and that is the amount of the weight. I do not know what the experience of other surgeons has been, but I have found this to be true, that a fracture of the femur will be put up with 20 pounds weight, and the surgeon will keep it on faithfully for say three months, or less—whatever time he thinks is necessary—having never changed the weight, making it more or less, and having paid very little attention as to what it is doing. It seems to me that that is altogether wrong. When you take one of these fractures into the hospital to reduce and try to pull it out—did you ever think how much weight you put onto it? Sometimes to get it out where you want it, you put on all the strength you have and maybe get somebody else to help you. So, consequently, it seems to me that there are many times where we can put on a very much greater weight than has been suggested here this morning. I think 30 pounds is the largest that I have

heard. I would say up to 50 or 75 pounds; but when I say that, just be careful! If you do not know when is the right time to take off the weight you are going to get into more trouble than you would if you did not put it on. That is what you have to look out for. Consequently, the question of watching the patient and knowing what to do at the right time is probably the most important part of the management.

There is just one other point that I want to emphasize. It was brought out by Dr. Reed. There is no time in the operating of a fracture that I feel so scared and really do not know what to do and how to do it and do it right as the matter of getting the patient back to the room and into his bed after I have operated him. Many times you will see a doctor operate the case, and then turn it over to the internes or to inexperienced nurses. I think the doctor should stay by his case absolutely until he sees that they are properly placed in bed, especially after operations.

DR. ROBERT EARL, St. Paul: I believe one of the most common faults in treating fractures of the femur with external traction is that the adhesive is not run far enough up on the thigh. Many men think that you should not put the adhesive any higher than the fracture. Some even stop it below the knee.

In surface traction the adhesive should be applied well above the point of the fracture, as high up on the groin and hip as possible, even if the fracture is in the lower part of the femur. In a fracture the lower end will be carried down by traction, the upper end being fixed. That the soft parts can be stretched and carried down below the proximal end of the fractured bone has been demonstrated in cases of amputation of the thigh in which the bone has been cut too long so the amputated end of the femur is exposed as much as two or three inches. In these cases, surface traction will pull the soft tissues down so they will unite over the end of the protruding amputated femur, demonstrating that surface traction can elongate the soft tissues.

Surgeons with very large experience, who have used as high as 50 pounds of weight, have never seen any damage done to the knee-joint by properly applied surface traction. The application of adhesive high up on the thigh, even when the fracture is in the lower third, relieves the knee of much strain.

When an anesthetic is given, the muscles should be over-stretched so as to partly paralyze them, after which not nearly so much traction will be required to maintain the desired length. If an anesthetic is not given, maximum traction should be used at the beginning when the ligaments are firm, as there is then less danger of producing relaxed joints than if gradually increasing traction is applied after the ligaments are softened.

Maximum traction at the beginning decreases the pain and gives better alignment before the blood clot at the site of fracture becomes organized.

DR. A. E. BENJAMIN, Minneapolis: There are one or two points that I think we should emphasize. The man who treats these cases, especially the general practitioner who takes them as emergency cases, does not need to be discouraged if the first x-ray does not show the proper

position. If you wait two or three weeks when the exudation is plastic, reduction can be made and the fragments retained more readily than at the primary reduction. That has been demonstrated in some cases I have had.

In regard to the operative procedure, I have found that there are certain classes of cases in fracture of the femur where the time saved in recovery of the patient pays one to operate; that is, if it is done with proper precautions and in the hospital. I think that when bone surgery first came out we were misled a little in the operative procedure; as were some who visited Lane and saw him operate in his small operating room where he could not turn around without a possibility of touching some of the instruments or the wound. The method which he employed interested many American surgeons. If a man is careful in selecting and operating his cases in bone surgery, he will get just as good results as in a laparotomy. There isn't any question about it. The bones and all the tissues heal as a rule. If he is rough and traumatizes the tissues and does not have them well protected—as I have seen some operators do—he will infect the wound. He may have four or five assistants pulling and tugging in order to get reduction and the bone in place and the plate on. If you are very careful to supervise the work at the time, I think you will get very good results; at least I have had in nearly all of my cases that I have operated upon.

Oblique fractures—particularly where they will not stay in place; the x-ray will show each time that they have slid some; no matter how much traction you put on. Such cases particularly are applicable for operative procedure.

DR. ARNOLD SCHWYZER, St. Paul: I believe that operations on fractures of the thigh are very seldom necessary. Some of the men who have discussed this have said that there were certain cases that they want to operate on. I would like to ask all of these men who have operated, what percentage of infection they get, and after they get it, what results do they have? Now these cases of Dr. Colvin's and these people who have gone across the stage here have had as perfect a result from a fracture of this kind as you could expect. I think it is, therefore, rather begging the question; and it is up to us to defend the men who are brought into court for malpractice. We should make it a professional, ethical question that if we have a doctor brought into court and his patient can go across the court room as these people have done, it is up to us to defend that man and say you absolutely can't get any better result. There are a certain number of doctors who would say if this patient were operated upon you would have a good anatomical result. Let them say how many times they have operated upon cases of this kind, and what percentage of results have been bad.

Now I have been all through this period of operating upon fractures of the femur. I have done some myself; I have seen a good many; and I know that the percentage of bad results is large. There are possibly in the very lowest part of the femur, where you would have a fracture into the knee joint, then I can see, in order to preserve the function of the knee joint, that it might be necessary to operate and put the two pieces together so that you would have a good functional result in the joint. But I think from this clinic that we have had from Dr. Colvin, that it shows us that

these fractures can be treated so that you will get a good functional result.

We must defend each other. A jury of laymen look at those pictures and say, "That isn't right." It is right, and we have to defend it. I have had people brought in to me with fractures of the two bones of the wrist, with an absolutely perfect functional result—could do anything; and they would say, "Well, here is the plate, and it is bad. The bones are not in place." I say, "What do you want? Suppose you do open it and you get rigidity of the tendons? The patient may go away with a perfect anatomical result, with a very poor functional result."

DR. H. B. SWEETSER, Minneapolis: I believe that open operations on fractures of the femur are very seldom necessary. Some of the men who have taken part in this discussion have indicated that they operate on a fair percentage of their cases. Now I would like to ask them what percentage of infection they get, and, when infection occurs, what is the final result? From my own experience and from my knowledge of the post-operative results of some other surgeons, who are skillful and careful surgeons, I suspect the percentage of infection is high, and the functional results following infection are bad, and may be fatal. Treatment without operation, whatever else may happen, at least is almost never complicated by infection.

These cases of Dr. Colvin's ought to and do carry to us a very graphic lesson. We look at his pictures and we say the anatomical results are poor and some of them bad. He then shows us the patients from whom these pictures were taken and gets them to walk across the stage, and we find that functionally the results are perfect,—no limp and normal movements. It has been said here that Dr. Colvin *might* get by, but that a man of lesser reputation would surely be mulcted for damages by a lay jury if such pictures were exhibited in court. I say that such a verdict ought to be impossible, no matter what the x-ray pictures show, if the patient can walk across the court room as these patients of Dr. Colvin's have walked across the stage here. We are looking for good functional results, and we should make it a professional, ethical question to defend any doctor, no matter how obscure his status, if his functional result is good, irrespective of what the x-ray shows.

I do not deny that there are some fractures of the femur in which an open operation may be necessary, and this is especially true of fractures which extend into the knee-joint, in order to restore even joint surfaces, but I think this clinic which Dr. Colvin has given us surely proves that the number of such cases must be small.

DR. H. W. MEYERDING, Rochester: It is very gratifying to me to find that the members of this symposium agree as well as they do upon the treatment of fractures of the femur. I do not recall hearing anyone advocate very strongly open treatment of fractures of the femur as a routine. We are all agreed that recent fractures of the hip are treated best by the Whitman closed method. We are not discussing malunion, nonunion or delayed union or osteomyelitis following infection. We seem to be agreed that the Thomas extension splint, as shown by Dr. Colvin, with certain modifications as used in various clinics, is the best means of treating fractures of the femur.

There are points in my paper which I did not get to,

such as of the articular fractures and epiphyseal separation. The question of joint incongruity and permanent partial disability comes up frequently following intra-articular fractures of the femur with displacement. We could discuss fracture all day and I am sure bring out new points constantly; however, there is not sufficient time.

I think lateral traction is very valuable where we have displacements such as some of the rays presented this morning showed. Five or ten pounds overhead traction or lateral traction often will help reduce and improve the position. Tight splinting, however, should be avoided; and the use of lateral splints, as formerly were so commonly used, led to needless atrophy and interference of circulation.

DR. C. A. REED, Minneapolis: Just a word in regard to these bad anatomical results and good functional results as shown by Dr. Colvin. I think we have all had that experience, and we will continue to have them; but some of our worst anatomical results will come out with pretty good functional results. I would like to ask if after a year or two these people could return to their original occupation, whether they had the full range of motion in the knee, and such things. But simply to repeat the findings of the British Medical Association Committee that while you might get brilliant functional results with an indifferent anatomical one—the surest way to get a good functional result is with a good anatomical one. I am sure that any of us could show pictures of better anatomical results and very much worse functional results. That is the type of case that we must try to avoid. It is not just a question of whether we have a few cases; the large statistics show that in good hospital practice the functional result is not good enough so that a very large proportion can go back to arduous labor.

DR. ALEX COLVIN, St. Paul: This is the man who had the double fracture of the femur; and we showed the rather awkward position of the fragments. He came in late be-

cause his machine broke down and he could not get here before. But he was very anxious to show what good legs he had. He whispered to me just now, when Dr. Reed said that he would like to see him a year from now, "Here is a year from now!"

I have accused myself a good many times of being a procrastinator and of not being progressive enough about fractures; and I will confess that occasionally I have missed an operation that I think I might have done. But I look upon an open operation for fracture of the femur as one of the biggest operations in surgery, and one of the most difficult to do, and one of the most difficult to get a result from after you have operated. It is a dangerous operation. People have lost their lives from it. They do not lose their lives from this kind of treatment. They do get functional results.

I think it is just as big a scientific accomplishment to treat a fracture non-operatively as by operation. Indeed, it is more scientific. There are just as many scientific principles involved in the proper treatment of fracture by mechanical methods as there are in operating upon them—even more. And I would say this, that I do not think any man is justified in operating on a fracture of the femur until he has proven to himself by sufficient experience that he cannot get a result by the ordinary mechanical methods; and I think there are very few men—at least comparatively few men; I am not speaking of men in the cities with big surgical practices, who get cases sent to them from all over—but there are very few men who through the country do some surgery and bone emergency surgery and all that sort of thing—there are very few men who have the experience which enables them to say to themselves, "I know that I can't get a result any other way." The only time I will operate on any fracture is where I can convince myself that "You can't get a result any other way; you have to operate." And there was not one fracture there that I felt I could convince myself sufficiently to say that.

"CHIROPRACTORS CLAIM RIGHT TO PRACTICE IN THE CITY HOSPITALS"

Under this caption the Jamestown Journal of February 7 gives a detailed account of a hearing before the city board of public welfare at which several chiropractors demanded the right to send patients to the city hospital and to treat any already there and desiring chiropractic treatment. "For two hours," says the Journal, "the 'back breakers' argued with members of the board and health officials, finally leaving when they were assured that the board will seek legal advice on the possibilities of allowing the hospital to be used for chiropractic treatments."

It is easy enough to understand the apparent lack of a sense of the fitness of things which prompted the chiro-

practors to present their demands thus openly, but not so easy to understand how they could hold the attention of an official board for two hours.

According to Mr. George W. Whiteside, counsel of the State Medical Society, there is no question but that chiropractors who practice what they are accustomed to call their "profession" are doing so in violation of the law of the State. "Chiropractic," he says, "is scientifically unsound and should be fought as a plague—its practice here is a crime which no political expediency can condone."

Assuming the correctness of this opinion, to permit them to practice in a public institution would be making the institution an instrument in the violation of the laws of the state.—*Health News, New York State Department of Health, March 3, 1924.*

SOME NOTES ON THE TREATMENT OF TUBERCULOSIS *

A. T. LAIRD, M.D.

Nopeming, Minn.

The successful treatment of tuberculosis depends on several factors. First of all the type of case must be considered, as results are possible for some patients that are not for others. The germ may have fallen in more or less refractory soil. A careful study of the history will show whether the patient comes from a "tuberculized" strain or a susceptible one; whether he has gradually become somewhat immunized himself; whether his surroundings and experiences have increased or diminished his resistance to infection; whether he has the mental and moral stamina to fight his enemy intelligently.

The duration of the infection and the degree of activity it has reached also affect the prognosis. Ordinarily it will be a simpler matter to secure satisfactory results in an early than in an advanced case. Frequently, however, a case diagnosed early will be found to come of non-resistant stock and run a rapid course. On the other hand, a moderately advanced case which has not been given a fair chance may do wonderfully well if placed under proper conditions.

Every effort should be made to secure earlier diagnosis through the study of contacts in infected families and by the fuller use of the diagnostic resources of general hospitals, every one of which should have open air wards where cases can be adequately treated while being studied. Routine physical examination of workers in industrial plants and the wider use of periodic physical examinations among apparently well people will doubtless bring to light many unsuspected cases.

In treatment various agencies and measures will be needed. The supervision of a case may have to extend several years and involve the use of a score of measures and agencies. Many of these will not be available in a practicing physician's office or in the patient's home. Usually it will be advisable for the patient to be in a sanatorium during some part of the treatment. The treatment may be outlined as follows:

TREATMENT OF TUBERCULOSIS

I. Active Stages:

A. General Measures.

1. Rest.
2. Open air.
3. Proper feeding.
4. Psychotherapy.
5. Supervision.
6. Correction of defects.
7. Careful nursing.
8. Symptoms.
9. Special treatment (Heliotherapy).
10. Specific treatment (Tuberculin).
11. Climatic treatment.

B. Local Measures.

1. Pulmonary Tuberculosis.
 - a. Control of cough.
 - b. Treatment of hemorrhage.
 - c. Treatment of pleurisy and pleural effusion.
 - d. Pneumothorax.
 - e. Thoracic surgery.
2. Laryngeal Tuberculosis.
 - a. Heliotherapy — general; local.
 - b. Local applications—sprays; direct applications.
 - c. Nerve injection.
3. Bone and Joint Disease.
 - a. Heliotherapy and light treatment.
 - b. Orthopedic measures and surgery.
 - c. Tuberculin.
4. Gland Tuberculosis.
 - a. Heliotherapy.
 - b. Tuberculin.
 - c. X-ray.
 - d. Surgery.
5. Other forms of tuberculosis.

II. Quiescent Stage:

1. Regulated rest and exercise.
2. Training in hygienic living.
3. Occupational therapy.

III. Apparently Arrested Stage:

1. Regulated rest and exercise.
2. Vocational conferences.
3. Study and supervised work.
4. Training in living with a handicap.

*Read before the Hennepin County Medical Society, Sept. 26, 1923.

IV. Arrested Stage:

1. Adequate follow-up.
2. Sheltered employment.
3. Gradual return to active citizenship.

1. *Rest* is our most powerful resource in fighting active tuberculosis as well as the best symptomatic treatment for hemorrhages, night sweats and cough. Dr. Peter Dettweiler, Brehmer's pupil and patient, was the first to utilize this resource fully and systematically. Dr. Joseph Pratt of Boston and Dr. Hugh M. Kinghorn of Saranac Lake have been particularly strict in its application. Dr. Marcus Paterson of Frimley Sanatorium in England has advocated the earlier and more strenuous use of exercise. During the activity of the disease there can be no doubt of the value of complete and prolonged rest.

2. *Open Air* has no direct action on the tubercle bacillus and is only one of many measures for increasing bodily resistance to the invading germs. Yet it is one of the very best. George Bodington of Sutton-Coldfield, Warwickshire, England, was one of the first to advocate its use, establishing a fresh air institution for the treatment of consumptives in 1840. His theories, however, did not gain much approval and Brehmer may be said to be the real founder of the modern fresh air treatment, applying it on a large scale in his sanatorium at Goerbersdorf, in Germany, about 1859. Its full application requires special equipment and technique, sheltered and screened porches, beds with easy running wheel castors, special methods of bed making, warm clothes for those who sit out of doors, etc. If these are at hand there are very few days in the year in temperate climates when outdoor life cannot be enjoyed. Automobilists find it possible to be comfortable out of doors, even in open cars, with the help of fur coats, foot warmers, etc., and patients should have all necessary equipment for outdoor living. Usually, especially for those who have lived indoors, there results a general improvement in nutrition, appetite, digestion, and sleep. Cough and fever are lessened.

3. *Proper Feeding*.—Various fads in the feeding of tuberculosis patients, such as overfeeding and high protein diet, have mostly passed out of fashion. A generous mixed diet, one that the patient can assimilate, is now considered the reasonable one. Special dietetic management will be needed in individual cases. In febrile cases it

should be simple. Milk alone may be used to advantage at times.

4. *Psychotherapy*.—The securing of the correct mental attitude on the part of the patient is usually the result of the co-operation of physicians, nurses and properly instructed relatives and friends. A patient may easily be over visited and over consulted on family affairs. His porch-mates may be too ready to discuss their symptoms at all times with him and such conversations should be discouraged. The stunned, panic stricken phase in which alarm is predominant should under favorable auspices give place to a calm facing of facts and realization of how large a portion of what makes life worth living can be salvaged. As soon as a man makes peace with his fate and faces it unafraid he has the mental attitude that helps recovery. Social service may relieve a man of worries about his family. Diversional craft work will show him that he can still interest himself in worth while accomplishment and get results. It will help him to stop brooding over his disease and to quit "practicing on a harp" as one of my patients said. Another mistake that patients often make is postponing interest in life until recovery, missing the enjoyment which is entirely possible to people who feel well and are given an enforced vacation in beautiful surroundings.

5. *Medical Supervision*.—The fact that the patient must develop habits of healthful living and that these must be drilled into him by precept and encouraging counsel makes continuous medical supervision most necessary especially in the active stages of the disease. This is one reason why the private physician, if he is unwilling to undertake the constant supervision of the patient himself, should not advise him or permit him to do without supervision, for instance "to go to a farm where there are plenty of good fresh eggs and milk as well as fresh air," but should rather refer him to a competent specialist or sanatorium for medical guidance.

6. *Correction of Defects*.—Frequently pathological conditions in the teeth, tonsils, pelvis, appendix or other organs obscure the symptomatology of the case and hinder recovery. Whenever possible these should be corrected early in the treatment of the case provided the operation itself does not do more harm than good. Ether anesthesia, especially if of long duration, is probably justly

held responsible for the lighting up of many latent tuberculous infections. Local anesthesia would be the preferable method in most cases.

7. *Careful Nursing*.—A skillful nurse trained in the technique of outdoor treatment and the rest cure can often turn the scale in the patient's favor, especially in the active stage of the disease. As tuberculosis is a common disease every nurse should be familiar with its care and a two or three months' course in the actual care of tuberculous patients in an affiliated sanatorium should be part of the curriculum of every nurses' training school.

8. *Symptomatic Treatment*. — Medicines of various kinds are needed now and then in most cases. Laxatives and astringents, expectorants and sedatives, hypnotics and alteratives all have their place. The routine use of laxatives can often be avoided by diet. Counterirritants and other local applications relieve pain. Opiates and other narcotics should be used with extreme care in the early stages of the disease on account of the danger of habit formation. In far advanced cases they can be used more freely. Palliative measures of various kinds can give a great deal of relief and comfort.

9. *Of Special Treatments* now in vogue, heliotherapy appears to be by far the most useful. However, it is not generally considered applicable to pulmonary cases. In bone and joint tuberculosis it has a most helpful influence on the general metabolism as well as upon the local lesion.

10. *Specific Treatment*.—The only specific treatment which is generally believed to have any value is the tuberculin treatment and this like heliotherapy is more useful in surgical and gland tuberculosis than in pulmonary disease. The method of Trudeau is the one generally approved in administering it.

11. *Climatic Treatment*.—Health resorts located in widely differing climates have been praised as suitable for tuberculous patients. The good reputation of some of them has been due to the excellent systems of treatment followed in them. Practically no climate is ideal throughout the year, and nearly every climate is good during a portion of the year. Northern Minnesota has a climate in many respects similar to that of the Adirondacks. Rest, peace of mind, good care, and proper food are obtainable near the patient's home. Home-

sickness and worry about finances are more common in distant health resorts. Leaving the home climate is usually attended with some risk and requires abundant financial resources.

The detail of local treatment need not be discussed at this time as we are making only a brief discussion of general principles.

Treatment in the Quiescent Stage.—While the patient is still at the sanatorium he may lose all essential symptoms and feel perfectly well. If this condition lasts two months his lesion is said to be "quiescent" according to the definition of the National Tuberculosis Association. Tubercle bacilli may or may not be present in his sputum. At this period the "administration" of exercise in gradually increasing doses is begun. The effect is to be judged by a careful study of the patient's condition at very short intervals. Records of temperature and pulse must be kept and the occurrence of unfavorable symptoms must be noted. The weight must be closely watched. In many cases the record may be kept by the patient provided his intelligent interest and co-operation are enlisted. Most sanatorium men do not try to secure definite auto-inoculation reactions by exercise after the method of Paterson. Some such plan of gradual increase as the following is usually employed.

EXERCISE ALLOWED IN DIFFERENT GRADES

1. Complete rest in bed.
- 1A. Rest in bed. Turning on side permitted.
2. Rest in bed. Patient allowed to turn on side and to sit up occasionally.
- 2A. Rest in bed. May use commode or go to bath room in wheel chair. Letter writing and reading by special permission.
3. Rest in bed. May walk to bath room. Reading and letter writing permitted. Light fancy work and light handicrafts allowed after special permission for not over one hour a day.
- 3A. Meals in small dining room. Other exercises as in preceding grades.
4. Meals in main dining room. Patient to return to room immediately after the meal.
- 4A. Reception room exercise. Short auto rides permitted, not over one-half hour. Attendance at entertainments allowed. Patient may remain downstairs after meals.

5. Fifteen minutes walking, besides exercise specified in second column. May spend evening in reception room, may attend entertainments and take exercise of preceding grades.
- 5A. Thirty minutes walking, besides exercise specified in second column. May take exercise of preceding grades. All handicraft work to be done in workshop. Permission to be secured for as much as two hours light work in all if done while sitting.
6. Forty-five minutes walking. Other exercises as in preceding grades.
- 6A. One hour walking. Other exercises as in preceding grades.
7. One and one-half hours exercise. Not over one hour walking. May work in office or do other light work up to three hours upon special permission. May take school work. Vocational training.
- 7A. Two hours exercise. Not over one hour of walking. May take exercise of preceding grades. Not over two hours of active exercise. May have up to four hours of light work or school work. Vocational training.
8. Three hours exercise. May be all work or part work. Not over one hour of walking to be included without special permission. Vocational training.
- 8A. Four hours exercise. Four hours light work or other exercise including walking. Vocational training.
9. Five hours exercise. Five hours work and other exercise including walking. Vocational training.
- 9A. Six hours exercise. Six hours work and other exercise including walking. Vocational training.
10. Seven hours exercise. Seven hours work and other exercise including walking. Vocational training.
- 10A. Eight hours exercise. Eight hours work and other exercises including walking. Vocational training.

Apparently Arrested Stage.—In the “apparently arrested” stage according to the National Association definition, symptoms must have been absent for a period of three months and tubercle bacilli must have disappeared from the sputum.

Having reached this stage in the return to health, the patient should make definite life plans and have special counsel in adjusting himself to a new kind of living. Those accustomed to heavy manual labor must in most instances choose a new vocation. Even very modest attainment in the study of English and in figuring may make it possible for a man to secure a position as supervising foreman or time keeper. For those who already have some education the state through its care for the handicapped offers special opportunities for instruction.

The actual performance of a certain amount of work at the sanatorium without relapse is the best guarantee that the patient can safely go home to less sheltered employment. The industrial colony at Papworth, in England, which operates in close association with a sanatorium, offers opportunities for intra-mural employment on a larger scale than any American institution, although most sanatoria have a few arrested cases among their employees.

Arrested Stage.—In the arrested stage, according to the National Association’s definition, symptoms and bacilli must have been absent for a period of six months. In most instances the patient will have left the sanatorium and be back facing the world again. Unless closely followed up he may return to the exact environment and working conditions that caused his downfall in the first place. He needs the counsel and encouragement of a physician familiar with his special problem and his work must be within his limited capacity. Often the way the hours are spent when he is not working determines his fate. An indoor occupation may be more suitable than an outdoor one that requires much muscular exertion. Working indoors a limited number of hours and sleeping out gives the patient as much fresh air as working out of doors and sleeping in.

As stated in the beginning of the paper many of the agencies which must be used in the treatment of tuberculosis are not within the control of any physician, yet at some time during the course of the treatment of nearly every case the private physician will have to shoulder considerable responsibility. He must ordinarily make the diagnosis and has at his call the resources of the general hospital. He should have the privilege of having his patient at the hospital and the hospital should provide suitable treatment for his patient while there.

The sanatorium has a definite place in the mechanism for securing the best results for his patient and the physician assumes a heavy responsibility who does not advise sanatorium treatment at the proper time. The modern sanatorium offers the patient the following advantages:

- Conveniences for "cure taking"
- Freedom from responsibility
- Constant medical guidance
- The moral support of other patients taking the same treatment
- Rest hours free from disturbance
- Nursing care always available
- Training in the protection of others from infection.

After a course of training at a sanatorium, home treatment is more likely to be successful than if attempted first. There is no reason, however, for sending moribund patients long distances to a sanatorium. They should be cared for at home or in a local hospital.

The responsibility for the medical follow-up of cases discharged from sanatoriums must rest largely with the private physician. The state will doubtless do much more than it has in affording him the counsel and active assistance of members of the sanatorium staff. This service can be furnished the physician along with free sputum examinations and other diagnostic facilities. To secure permanent results there must be active co-operation between the physician and the sanatorium. The physician must be familiar with the special form of home treatment required, and for this purpose the general hospital must provide him actual experience and training.

The sanatorium needs the skill of the hospital staff in the treatment of surgical complications and special conditions.

The treatment of a case of tuberculosis may last many years. The patient may promptly get well or die; on the other hand, he may neither get well nor die and for a series of years may be a decidedly handicapped citizen. That he have the maximum degree of health possible and be as much of an asset to the community as his health will permit requires the co-ordinated work of physicians and sanatoria as well as of other agencies. The State Advisory Commission is directing the work in Minnesota and should have the cordial co-operation of every physician and every institution.

OSTEOCHONDROMATOSIS OF THE HIP* JOINT*

MELVIN S. HENDERSON, M.D.

Section on Orthopedic Surgery, Mayo Clinic
Rochester, Minnesota

Osteochondromatosis is a rare pathologic condition of the synovial membrane found in certain joints, bursæ and tendon sheaths, in which the stratum synoviale takes on the property of forming osteocartilaginous bodies. The recent work of Jones in which he thoroughly searched the literature and studied the twenty cases that had been observed in the Mayo Clinic until November, 1923, gives further weight to the theory that the condition should be classified as a benign neoplastic process. Since the completion of this study, a patient has come under our observation with the condition in the hip joint. This is the only patient in our series whose hip joint is involved, and we have been able to find only one mentioned in the literature, that by Eden, in 1914.†

ETIOLOGY

Various etiologic hypotheses have been advanced; these may be grouped as infectious, traumatic, embryologic, and neoplastic. Most writers have been inclined to place little value on infection as an etiologic factor. Some of them, however, lean toward the infectious theory (Bolton, Halstead, Reichel and Hahn). Jones, after reviewing the literature and our cases, concluded that infection did not play a part of any consequence in the etiology. Trauma has been stressed by certain writers (Humphry, Davis, Carothers, Henderson, and Fisher) as an etiologic factor, and Jones, in reviewing our records, found a definite history of trauma, usually long before finding the loose bodies, present in eight.

The fact that all the tissues involved in this process are developed by differentiation of the same mesenchymal tissue is emphasized by Whitelocke, Lotsch, Henderson and Fisher. During development in the embryo, some of these cells degenerate to form the joint cavity, some differentiate to form the joint cartilage, and some to form the synovial membrane. This embryologic theory is closely al-

*Read before the Minnesota Academy of Medicine, St. Paul, February 13, 1924.

†In the interval between sending this article in for publication and receiving the proof, we have operated on another patient with loose bodies in the hip, and removed twenty-seven bodies, fourteen attached by pedicles and thirteen free. A posterior incision was used.

lied to the neoplastic, and it is necessary to accept this basis before the latter is discussed. Ziegler defines a neoplasm as "a new formation of tissue, apparently arising and growing independently, having an atypical structure inserted uselessly into the organism, possessing no function of service to the body, and showing no typical termination of growth." Osteochondromatosis grows slowly, is expansive rather than infiltrating, mitotic figures are absent, it is encapsulated, never metastasizes, does not tend to recur after removal, and is composed of well differentiated cells. These findings are characteristic of benign neoplasms, and therefore it is logical to classify osteochondromatosis with this group.

PATHOLOGY

Joint capsules are composed of two layers, a stratum fibrosum and a stratum synoviale, the former characterized by dense connective tissue, the latter by loose connective tissue containing fat, blood vessels and lymphatics. The stratum synoviale has an inner smooth lining, composed of parallel fibers of connective tissue and round or stellate cells with large nuclei. In areas of unusual pressure these cells with the large nuclei are infrequent, in others they are arranged in a single layer, whereas, especially in the crypts and pockets and margins of the joint, this mesothelium may be three or four cells in thickness (Lewis and Stöhr). Laennec, Rokitansky and Brodie thought that the bodies might arise from either layer, but Kölliker and Eden believed that they came from the stratum synoviale. Jones, from his study, concluded that the bodies arose from the stratum synoviale. Müller, Hagemann, Kienböck and Henderson mention that the point of origin frequently is at the juncture of the joint capsule with the periosteum, where the mesothelial cells are in greater number. However, there is no doubt but that any portion of the synovial membrane may be the site of the bodies. They may start either as osteomas or chondromas. The cartilage may be hyalin, fibrous, calcified, or a combination of these forms. Bone in these bodies may be developed either directly from connective tissue by the membrane method, or by preformation in the cartilage. The most typical form is a spherical shell of bone surrounded by cartilage and fibrous tissue, and filled with vascular fat and spurs of bone. The bodies are at first attached by pedicles, through which they get their blood supply. Due to their becoming larger and heavier, and the nat-

ural trauma associated with joint motion, they finally break their pedicles and wander as free loose bodies. The question as to whether the bodies receive sufficient nourishment from the synovial fluid to increase their size is not definitely settled, but the fact that, on studying a section of a free body we find the outer layer of cartilage in an excellent state of preservation, the nuclei staining well, whereas deeper in the body the cells show evidence of degeneration, would lend weight to the theory that the fluid does nourish the body. It seems probable, although it is not proved, that cartilage may proliferate under these conditions. In the detached bodies the bone is invariably found to be necrotic, whereas in the attached bodies with a blood supply, growing bone is found.

SYMPTOMS

The symptoms vary with the joint involved, according to whether the bodies are numerous, still attached, or free, their size, and so forth. Often the first complaint is of a little stiffness and inability to put the joint through a full range of movement. The common symptom is, of course, catching or locking of the joint, causing pain and a feeling of insecurity. Objectively the bodies may or may not be palpable, depending on their number and size, and the covering over the joints.

Fig. 1. Loose bodies in left hip joint.

REPORT OF CASE

Case A446938. The patient, aged thirteen years, presented himself for examination November 9, 1923. He was well developed, 5 feet, 4 inches in height, and weighed 115 pounds. The family history was negative, and he had had

no infectious diseases. Seven and one-half years before, when he was six years of age, a ladder, which he was climbing, broke, and he fell a distance of 15 feet, landing on his feet. He was not badly hurt, but limped on account of pain in his feet. The following winter while skiing he spread his legs to such a degree that it hurt him considerably, and he could remember limping for quite a while on account of pain in the hip. In the summer of 1922 he was

Fig. 2. Site of origin of bodies.

thrown from a truck, striking hard on the left hip joint. After this there was slight pain on movement of the hip. Four weeks before our examination, while riding his bicycle, he had an attack of quite severe pain, and a locking of the left hip lasting ten minutes before he was able to limp home. He kept quiet for a week, and although the hip has been sore and painful, he had had no more lockings. He walked into the office with a slight limp, but without cane or crutch.

Physical examination and examination of the urine and blood were essentially negative; the Wassermann reaction was negative. There was slight restriction of motion of the left hip joint in all directions. On flexing the hip, thus relaxing the anterior capsule, a mass could be felt, and some of the bodies could be palpated. The x-ray disclosed multiple loose osteocartilaginous bodies in the left hip joint (Fig. 1). Roentgenograms were made with the hip in inversion, eversion and in the straight position. It was impossible to count the bodies, but it was thought that there were between twelve and twenty.

The joint was exposed by a small Smith-Peterson incision running parallel to the long axis of the neck made into the capsule, and a number of free osteocartilaginous bodies, thirty-one in all, were removed. The gloved finger was then introduced, and an enlargement resembling an exostosis (Fig. 2) could be felt anteriorly at the point where the

synovial membrane was reflected from the anterior intertrochanteric line. This appeared to be the main site of the origin of the loose bodies, the mass having its origin just where the synovial membrane was reflected from the bone. This exostosis was smoothed down by the chisel and a thorough search of the joint for the loose bodies made by aid of a gallbladder scoop. A slightly movable, encapsulated mass could be felt at the point where the synovial membrane was reflected from the acetabulum at the upper border, and on cutting into this, two loose bodies popped out, indicating that the bodies had their origin not only at the site of the exostosis, but elsewhere (Fig. 2). As nearly as could be ascertained by visual inspection, which was naturally limited, and by palpation, the picture was not like that seen in some cases of osteochondromatosis, in which the synovial membrane is studded with bodies. The bodies varied in size from 1.5 cm. to 4 mm. (Fig. 3). Microscopic sections showed cartilage and bone in varying amounts, the amount of bone being greater than usual (Fig. 4). We did not feel sure that all the bodies had been secured, particularly from the posterior part of the joint, but I was unwilling to make a posterior incision at this time. The operation had already taken thirty minutes, and although

Fig. 3. Thirty-one loose bodies removed.

the patient's condition was excellent, I felt that the risk of infection would be increased by further search through another incision. The incision was closed and the patient put to bed without a cast. His convalescence was uneventful and he went home on the tenth day with motion quite free. A roentgenogram (Fig. 5) taken after operation showed that some loose bodies were still present. The patient and

his family were acquainted with this fact and told that if further symptoms arose, he was to return for exploration by a posterior incision.

Comment.—The history and findings in this case serve to emphasize certain points and facts concern-

Fig. 4. Section of loose body illustrating endochondral ossification. (a) Dark area represents cartilage. (b) Lighter area represents bone. (c) Fibrous tissue. Both cartilage and bone were necrotic.

ing osteochondromatosis. The condition was longstanding, and the patient had sustained three severe traumas to the left hip joint. Severe pain finally forced him to seek relief. In this case, therefore, from an etiologic viewpoint, trauma was a definite factor. At operation a definite tumor formation was found on the anterior intertrochanteric line (Fig. 2), at a point where the synovial membrane was reflected from the bone and where the stratum synoviale was probably three or four cells deep. We found, also, two bodies in a pocket at the superior margin of the acetabulum (Fig. 2) where the synovial membrane was reflected from the bone. These findings serve to corroborate the embryologic and neoplastic theories mentioned. Although Eden's case was the only one we found reported in the literature, undoubtedly other cases have been seen and treated surgically. Possibly they have not been reported, or are so buried in the literature that we could not find them. Eden treated his patient radically, performing an excision. The patient later was able to carry on his duties as a hospital orderly. From our standpoint this procedure appears too radical. Our patient is young, and if he has further trouble, there will be ample time to consider more radical procedures.

First of all, the health officer must in his own heart entertain for the medical profession the highest degree of respect. The health officer who outwardly cultivates the medical profession and who inwardly has contempt for their attainments in the public health field is sure to be found out. This does not mean that the health officer must or that he can regard the members of the medical profession as experts in public health. Distinctly they are not, but the fields of public health and medical practice have certain things in common, while, outside of this common ground, each profession covers much not included in the other. It should be the aim of every health officer to have very clear ideas concerning this common field, and in it to secure complete co-operation of the two professions.

At this point it may well be asked just what right has a health officer to feel that he is entitled at all times to the cordial support of the medical profession. This question has often been answered by stating that the medical profession differs from all other human callings in that its members are frankly devoted to the betterment of humanity and that, for this reason, they should always be willing not only to respond to all demands for charity work but should also regard it as their special privilege to give freely of their time in promoting the cause of public health.

While there may be much in this argument, it is safer to assume that doctors, first of all, are men constituted as are other men, having their own livelihood to consider and not receiving such special consideration from the general public as calls for their giving to the public more than do the members of other professions.—*E. C. Levy, M.D., Am. Jour. Pub. Health, Dec., 1923.*

THROMBO-ANGIITIS OBLITERANS: WITH CASE REPORT*

H. W. CHRISTIANSON, B.Ph.M., B.Sc., M.D.

Wykoff, Minnesota

Thrombo-angiitis obliterans is a disease of unknown origin of the blood vessels or blood, characterized by obliteration of the vessels of the extremities, and followed by certain trophic and vasomotor disturbances.

Etiology.—It is a comparatively rare disease. It was first fully described by Leo Buerger, of New York. He believes it to be of an infectious origin of unknown etiology. Almost all of his cases occurred in young men, twenty-five to forty years of age, and of Hebrew descent, who were as a general rule heavy cigarette smokers. Willy Meyer¹ believes that the smoke poisons from cigarettes affecting a previously weakened nervous system may be largely to blame. Heredity probably plays no part, although more than one case in the same family has been reported. There is no connection between this disease and diet; since it occurs in males and not in females, some have advanced the theory that the endocrine glands play an important rôle. There are no known infectious diseases that are precursors of thrombo-angiitis, although typhoid fever is blamed by a few.

T. Mayesima² advances the theory that there may be an increase in the viscosity of the blood that is responsible, and Willy Meyer¹ further explains it as due to a change or disease of the blood itself that may cause the blood to coagulate when it flows through vessels of smaller calibre.

Pathology.—Leo Buerger³ describes it as an occlusive thrombosis of vessels with inflammatory reactions of vessels and with the end result of ulceration and gangrene. Veins either superficial or deep or both are involved in about 40 per cent of the cases.

He finds that it is a thrombotic process in the arteries and veins, occurring usually in the larger vessels, starting distally and working up. The thrombus is a red or mixed clot with giant cells, leucocytes, and disintegrated cells. The process is preceded, probably, and accompanied, by acute inflammatory changes and followed by organization and canalization of thrombus. Surrounding the ves-

*Presented before the annual meeting of the Minnesota State Medical Association, St. Paul, October, 1923.

sel there is usually fibrotic tissue that binds down artery, comites and accompanying nerves.

Laboratory Findings:

1. Chemical blood examination.

Bernhard⁴ found that the chemical blood examination was normal for its nitrogenous constituents, cholesterol, chlorides, the carbon dioxide combining power of the blood plasma, and calcium. However, he found a definite hyperglycemia reaction peculiar to this disease.

2. Microscopical blood examination.

H. M. Thomas⁵ reports a case of persistent leukocytosis.

3. Stomach analysis: negative.

4. Roentgenolgy: negative.

Bones show no changes until attacked by gangrene or osteomyelitis, which usually occurs late in the disease.

5. Basal metabolism: normal.

Symptoms.—The symptoms at first are rather vague, and often diagnosed as rheumatic, weak foot, frost bites, et. cetera. Among the first symptoms are pain in the extremities, coldness, tingling, and cyanosis. As the disease progresses, the pains usually increase in severity and may become excruciating, or may take the form of intermittent claudication; the pain may be absent. The extremity usually assumes a congested appearance—rubor—in the dependent position, or a waxy livid hue when elevated. There is either an absence of the pulse or a very faint one, depending on the stage of the disease. There may be scattered phlebitis—the patient complaining of “hard lumps” or “strings” under the skin. Ulcerated areas usually form, which are very rebellious to treatment. The ulcerated condition may heal, and subsequent ulcers may form, which eventually develop into gangrene. This may be a wide, rapidly spreading gangrene, or it may be confined to the distal digits. The lower extremity is usually involved—very rarely the upper.

To sum up we may say that the important symptoms are pain, intermittent claudication, scattered phlebitis, rubor or blanching of foot depending on posture, disappearance of pulse, ulceration and gangrene.

Complications.—As this is usually a chronic disease, any of the infectious diseases may complicate it and end the scene.

As these individuals suffering from it are more or less of a neurotic temperament, they get to worrying about their condition, so it is not uncommon

to find various mental states. Some even get so mentally deranged as to commit suicide.

Moist gangrene and pyemia are most to be dreaded, as when these develop they are usually fatal.

Diagnosis.—The clinical diagnosis as given by Buerger⁶ rests upon the following:

1. “The racial (Hebrew) and sex (male) predilection.
2. The early involvement of the lower extremities.
3. The early symptoms of pain or intermittent claudication.
4. The presence of migrating phlebitis.
5. The evidence of pulseless vessels.
6. The presence of blanching of the extremity in the elevated position.
7. The existence of rubor in the dependent position.
8. The relation of hyperemic phenomena to posture.
9. The absence of simultaneous, symmetrical involvement.
10. The slow, progressive chronic course terminating in gangrene.”

Differential Diagnosis.—The diseases that may be confused with thrombo-angiitis obliterans are Raynaud's disease, scleroderma, sclerodactyl, syphilis, tuberculosis, diabetes, arteriosclerosis, erythromelalgia.

Raynaud's disease is a disease of unknown etiology. Its pathology is not exactly known. The lesion is thought to be somewhere in the central nervous system. There is alternating blushing and blanching of the foot. This disease is characterized by intermittent attacks with normal intervals. The pain has always a distinct nerve distribution, and usually in symmetrical parts. The areas affected in the thrombo-angiitis obliterans always correspond to the vessels affected, which is not true of Raynaud's disease. There is always atrophy of the distal phalanges in Raynaud's disease which you do not find in the thrombo-angiitis obliterans, until gangrene has advanced to such a degree as to cause definite changes in the bones.

Diabetes and senile gangrene are usually easily differentiated by the physical and laboratory findings.

In erythromelalgia the plantar surface of the foot is red and glistening while the rest of the foot is pale and atrophic.

Both scleroderma and sclerodactyl can be differentiated by the fact that there is atrophy of the distal phalanges, and by the first stage of hard edema.

In syphilis there are usually other signs of syphilis present along with a positive Wassermann.

An ulcerated condition in cutaneous tuberculosis is usually accompanied by changes in the lungs, and in the later stages it is easily distinguished from thrombo-angiitis obliterans.

Course.—Thrombo-angiitis obliterans runs a chronic course. It usually starts with vague rheumatic-like pains, intermittent limping, ulcers, and finally gangrene develops. It may end fatally either by wide spreading gangrene, pyemia, or by thrombosis of some of the important vessels to the brain, liver or lung, or by some other intercurrent disease. Some cases seem to recover entirely.

Treatment.—The treatment may be either medical or surgical or a combination of both. Emphasis cannot be laid too strongly on the conservative treatment first, which of course entails an early recognition of the disease. Many a case is reported in the literature where a wrong diagnosis was made, and treatment instituted that resulted disastrously for the patient. Any local surgery of the ulcerative process in the disease will invariably end in gangrene.

Steele,⁷ of Philadelphia, uses large doses of 2 per cent sodium citrate intravenously along with hot air locally and 10 grains of potassium iodide, internally three times a day. His treatment is carried out over a long period of time—a year or more.

Sinkoe,⁸ of Atlanta, has successfully used the Bier's suction apparatus.

Willy Meyer⁹ advocates the use of Ringer's solution by hypodermoclysis in conjunction with intravenous solutions of sodium citrate, glandular extract, and, if needed, conservative surgical treatment.

H. F. Wolf¹² has been successful with diathermia.

After gangrene has set in it is best to mark time, if possible, with intravenous solutions of sodium citrate, hypodermoclysis of Ringer's solution with potassium iodide internally, heat and massage until there is definite demarcation, and then do as little surgery as is consistently needed.

High amputation should not be resorted to unless all other measures fail, and the patient is in great danger of his life.

All foci of infection should be removed.

Arterio-venous anastomosis has not been successful by all that have tried it, so it is not to be recommended as a primary measure.

Heat or Bier's suction apparatus are both undoubtedly of some value.

The following case is interesting because it emphasizes the need of very careful histories and examinations, before minor surgery of the feet should be undertaken. There are a number of cases reported where the patient suffered the same consequences as this one did, just because the surgeon was too ready to use the knife. Mr. H. D. had an ulcerated condition under his big toe which had resisted all home treatments. He consulted an orthopedist, who immediately excised the ulcerated tract and put on a salicylic acid dressing, to remove the remaining calloused condition. In about twenty-four hours the foot became greatly inflamed, and painful and in another thirty-six hours gangrene had set in.

It is interesting from another standpoint because this patient was not of Hebrew descent, as are most of the cases reported.

Before presenting this case due credit must be given Dr. Edward Evans, of La Crosse, Wis., for making the diagnosis.

Present complaint. Mr. H. D., aged 37. A lumberman by trade, came to me on November 24, 1921, complaining of an ulcerated condition under the proximal phalanges of big and little toe.

Family History. Father living and well at the age of 62. Mother died at age of 65, from heart failure. It is interesting to note that the mother always had trouble with her feet. She was troubled considerably with rheumatic pains in the legs and never was able to walk any distance without resting. It was common to have her complain bitterly at nights with severe cramps in her thighs. Two brothers living and well. One sister dead, of measles. Otherwise family history was negative.

Marital History. Married 15 years. Two children living and well. No miscarriages. Wife living and well.

Occupational History. Lumberman for last eighteen years.

Past History. Previous health: He always enjoyed fairly good health. He has had considerable trouble with his feet for last fifteen years, and in 1903 he had typhoid fever. Tonsillitis often while a child. No other diseases.

Venereal: Negative.

Head: Negative.

Cardio Respiratory: Occasionally some dyspnea on climbing stairs.

Gastro Intestinal: Negative.

Genito Urinary: Negative; no symptoms of diabetes.

Skin: Negative, except for calluses under right foot.

Weight: About normal.

Habits: He was not a total abstainer of liquor, but very seldom used same to excess. Smokes about twenty cigarettes a day and cigars and pipe occasionally.

Present Illness. Patient has had rheumatic pains in his feet for years and for about the last ten years has had occasional spells of severe cramps in thighs, coming on shortly after going to bed and lasting from fifteen minutes to three hours. These pains have been coming on more frequently and severe during the last few years. Lately has had pains in calves of legs on walking any distance, which disappeared on resting. In the fall of 1919 he developed an ulcer under the big toe of the left foot, and about six months later developed one under the right big toe. The left toe healed up in about six months. The treatment consisted of hot foot baths, and frequent applications of a mild antiseptic. The ulcer under the right big toe has resisted all treatment.

Physical Examination. Patient a well developed male, age 37, of French, Irish, and German descent.

Head: Negative.

Neck: Negative.

Thorax: Negative, except for slight mitral regurgitation.

Abdomen: Negative.

Extremities: There is a perforating ulcer under the big and little toe of right foot, with considerable callus formation surrounding. The foot assumes a congested mottled appearance in the pendent position, and pale appearance in the elevated. There is an absence of the pulse in the anterior and posterior tibial in the right leg and dorsalis pedis in the left but it is present in the popliteal. There is an old scar on the left big toe from a previously healed ulcer.

Reflexes: Normal.

Blood Pressure: Systolic 125, diastolic 80.

Hemoglobin: 85 per cent. **White blood cells:** 9,500.

Urinalysis: Negative.

Course. In February, 1922, patient consulted an orthopedist, who immediately cut out ulcerated edges and put on a salicylic acid dressing, on the calluses. In a few days gangrene set in, involving three of the toes and an area on the dorsum of the foot. On February 21, 1922, the patient consulted Dr. Edward Evans, of La Crosse, Wis., who made a diagnosis of thrombo-angiitis obliterans.

Patient on admittance to the hospital presented the following: Temperature 102 degrees, pulse rate 100, respiration rate 20. Right foot was very considerably swollen for a couple inches above the ankle. Great redness of the whole dorsum of the foot, though plantar surface was not swollen or reddened. The little toe was entirely gangrenous, black, dead, and the metatarsal phalangeal joint of this toe was open and the bone exposed. Under the ball of the great toe there was a small perforating ulcer which did not seem to reach the tendon. There was some blistering and blackening of the skin and one small superficial patch of gangrene just back of and outside the nail; did not seem to be any suppuration under the nail. The patient had the history of having had quite a high fever.

The subsequent course was one of progressive gangrene with infection until all the toes excepting the middle were involved. The foot was entirely healed by April, 1923.

However, it is still cold and clammy and has only faint pulsations in vessels and becomes edematous, if it is used very much.

Clinical Laboratory Reports. Urine showed a trace of albumin on three occasions, while in hospital. Blood examination, Feb. 21, 1922: hemoglobin 96; red count, 4,200,000; white count, 16,000; polymorphs, 94 per cent; blood sugar, .09 per cent. Patient has shown a persistent leukocytosis ever since.

Roentgenology report: Negative.

Treatment. The treatment consisted of heat, intravenous injections of 2 per cent sodium citrate or normal saline, massive internal doses of potassium iodide, mild antiseptic local dressings, and conservative surgical treatment. Patient was given in all about fifteen intravenous injections, of either normal saline, or 2 per cent sodium citrate. Two hundred to 800 c.c. were given at each injection.

Two minor operations were performed by Dr. Edward Evans.

The first one consisted of removing some dead gangrenous and infected tissues, on the dorsum of foot, and opening wider the sinus under the little toe, to permit better drainage of pus.

The second one was performed about five months after gangrene had started and consisted of removing stump of big toe, back to tarsal bone, as there was a persistent infected sinus at base, and amputation of second toe, as this also had a persistent infected sinus leading to its proximal joint. During this operation it is interesting to note that there was very little blood lost, about twenty drops, showing a very poor circulation. No sewing was undertaken. The foot healed completely in about nine months after last operation was performed.

Conclusions. This is undoubtedly a case of thrombo-angiitis obliterans. There are a few points of special interest in connection with this case, namely:

1. The patient was not of Hebrew descent.
2. The value was shown of a careful history and physical examination before any surgery of the extremities should be undertaken.
3. There has been undoubtedly a persistent leukocytosis present in this patient, analogous to the case reported by H. M. Thomas.⁵

DISCUSSION

DR. J. F. CORBETT, Minneapolis: I am very glad that Dr. Christianson has taken the time and made the effort, in a very busy life, to give us this carefully prepared paper. Now, why is thrombo-angiitis obliterans an important subject? In the first place, it affects young individuals; in the second place, it is a slowly progressive disease—it will go through a long series of years; and, in the third place, it is usually an intensely painful disease.

In the early diagnosis we have no cardinal points that I can enumerate. These cases sometimes present a picture of an osteomyelitis. Frequently they are operated upon for osteomyelitis of the great toe, probably due to the fact that the bones early undergo a lack of nourishment. Other cases are thought to be cases of neuritis. All cases have an antecedent history of pain and usually the characteristic of the pain is that it comes on with exercise. An individual may be perfectly free from pain for a long period of time. Let him walk six blocks; then the pain comes on and it will be so intense that, no matter where he is, he will stop and try to support himself in some way and rest his leg.

Early there is a change in the vessels. Oftentimes before gangrene develops, before we have absolute characteristic local appearance, the vessels can be distinctly palpated. Unlike senile gangrene this does not start at the periphery and work backwards, but is very apt to involve some of the larger vessels early. Moszkowicz's test for the collateral circulation, palpation of the superficial arteries for pulsation, palpation for consistency, are important points.

Now, what is there in the treatment? Amputation is a very poor treatment for thrombo-angiitis obliterans. We have been taught, as a surgical principle in senile gangrene, to operate at the lower third of the thigh; but amputation at the lower third of the thigh in thrombo-angiitis obliterans is often followed by some disastrous consequences. Any local operation, I believe, is apt to be followed by very severe and disastrous consequences unless very careful tests of the collateral circulation have been made and the proper point of amputation is selected.

Then what have we in the way of treatment if amputation and operation is not available? Bier's treatment properly applied—and by Bier's treatment I do not mean what is so commonly understood as Bier's hyperemia, which is mainly the application of elastic bandages, but rather the obtaining

of hyperemia through the agency of heat. Bier has published a beautiful little monograph, telling us exactly how to use Bier's hyperemia treatment of hot water; go from mild cold water to mild warm water and as time goes on increase the range of temperature, and by that means put the vessels through a course of gymnastics. Sometimes the patient has so much pain that he will not do that and I have used another expedient, that is to develop collateral circulation by the application of moist heat at the exposed points of the vessels, for instance, the popliteal space or in the groin.

I have seen a man with one leg already amputated, with a sloughing stump, with some process manifest in the other leg, where disaster seemed inevitable, to yield to this sort of treatment. If the condition was very severe, simply wrapping the affected part in heavy cotton and keeping it warm has sometimes allayed that sort of a condition. The use of citrate, I believe, has not passed the experimental stage. At one time we were giving subcutaneous injections of Ringer solution, but that has been abandoned. Most successful results have been obtained by the use of the Bier hyperemia treatment.

DR. EMIL S. GEIST, Minneapolis: Dr. Christianson has given a good exposition of practically all we know at this time regarding this mysterious ailment. He reports a rather advanced case in which progress was very favorable. Unfortunately, this does not happen in those advanced conditions where extensive gangrene has already set in. I am sure that Dr. Corbett did not want to say that amputation is never necessary, because in advanced cases amputation occasionally is indicated. When amputation is indicated it should be high, above the knee and above the bifurcation of the femoral artery.

Some months ago I prepared a paper on foot conditions which will be published shortly, which involves the study of seven hundred eighty-one consecutive cases of foot disability. In twenty-five of these cases, the foot complaint was directly attributable to interference with the arterial circulation. The symptoms were usually bilateral, it usually appeared in Jewish males, the average age was fifty.

As to symptoms, there were pain at night, cramps on use, complaints of feet getting cold easily; sometimes there occurred swelling and numbness; the dorsalis pedis pulse was absent in all of them. X-rays occasionally showed atheromatous changes. The wearing of arches and braces usually increased the discomfort. There is no doubt in my mind that tobacco, coffee and other stimulants play a considerable rôle in the etiology of this ailment.

As for treatment, Dr. Christianson has well and wisely outlined the treatment of these early cases, based upon the early recognition of the disease. In addition to what has already been said regarding therapy, heliotherapy should be considered. I believe that this remedial measure is distinctly indicated and has been of distinct benefit in a considerable number of my cases. During the past few years, Koppis, Schmaff and others have operated on the femoral artery, doing what is termed periarterial sympathectomy. I have had no experience with this operation.

DR. EDWARD EVANS, La Crosse, Wis.: Those of us removed from the large centers of scientific investigation, reading the literature of thrombo-angiitis obliterans, I

think get more confusion from it than anything else. Apparently very little is yet known about the fundamental underlying pathology of the disease. The case report as given so splendidly by Dr. Christianson was, I think, undoubtedly a case of this sort. Until we know more about its underlying pathology I think we have only to go along experimentally, feeling our way and, as Dr. Corbett has said, not do too much.

One thing I would like to say, as one who has been interested for a very long time, both actively and otherwise, in state medical associations, I cannot help saying that I feel it is a splendid thing when you men make up these programs for the state societies to get young men from small places engaged in the general practice to present papers. I think it was Sir James Mackenzie who said that until we get back to the clinician who first saw the case and get his viewpoint of it, we are not going to get very far along clinical lines. I am mighty glad to know that Dr. Christianson, in spite of the demands upon his time through his busy practice, found the time and had the scientific spirit and clinical acumen to present a paper like that to this society.

DR. MOSES BARRON, Minneapolis: This subject is very interesting because it deals with one of those diseases concerning which we know very little. I had the opportunity of studying two cases. Both of these patients were Russian Jews. The two types of treatment suggested were used in these cases. The first case was that of a man about forty-five years old who had had a history of pain in his foot extending over a period of about twelve to fourteen years. I saw him in consultation with a surgeon and at that time there was an area of gangrene over one of the toes. He was complaining of severe and excruciating pains. He was sent to a hospital and there he was given repeated injections of sodium citrate. At first it was thought there was some improvement, but later the pain became severe again and an operation was advised. A low amputation was performed, but gangrene set in in the flaps and the leg had to be re-amputated higher up. Shortly after this, however, the patient died.

The second case is of unusual interest. This patient also was in the forties. He had complained of pain in the toes of one of his feet for a long time. The pain was constant and so severe that he could not get any rest. Many nights he would not get more than one or two hours of sleep. He would pace the floor most of the night. He consulted one

doctor after another without much relief. He had visited doctors in other cities. I happened to see him during several of his attacks of pain at night. The history together with the appearance of the foot suggested strongly thrombo-angiitis obliterans. He was being treated at the time by a surgeon with heat and other measures with very little relief. He then developed pain in the great toe of the other foot. He was advised to see a chiropodist, who at once diagnosed it as an ingrown toe-nail. The chiropodist attempted to treat the toe-nail. This resulted in infection and a rapidly spreading gangrene of the great toe. The gangrene was spreading so rapidly that the surgeon was at once called and the patient ordered to the hospital for operation. An amputation was performed rather high up the leg. The patient made an uneventful recovery, and the very striking feature of this case is that he has had practically no pain since in the originally affected leg, though it was the other leg which was amputated. I examined the tissue of the amputated leg. It was typical of thrombo-angiitis obliterans. The anterior and posterior tibial arteries with their branches appeared like pipe stems, or rather cords of tissue. Microscopically, they showed the lumina occluded with the fibrosis, in some areas showing blood pigments as from an organized thrombus. There was a leukocytic infiltration throughout the blood vessel walls extending into the adventitia. The gross and microscopic pictures were identical with those described by Buerger.

The interesting facts in the above cases are that one man was treated with sodium citrate with no relief, and later he died following amputation. The second case was not treated with sodium citrate but relief was obtained by having the other leg amputated than the one which gave him the excruciating pain. The diagnosis of this case was established by gross and microscopic study.

DR. H. W. CHRISTIANSON (closing): I have been asked why it attacks the Jews more frequently than other races. I think that it is Willy Meyer, of New York, who believes it is partly due to a previously weakened nervous system. That is, the Jews have been oppressed for many centuries and consequently have acquired a neurotic temperament. He believes that for this reason, the disease is more prevalent among the Jews.

The blood pressure determinations are usually sub-normal. However, although the determinations usually run from sub-normal to normal, exceptions show a slight rise. The reason for this, I cannot explain.

STUDENTS' HEALTH SERVICE AT THE UNIVERSITY OF MINNESOTA

H. S. DIEHL, M.A., M.D.

Director, Students' Health Service,
University of Minnesota

Minneapolis

Although for ten to fifteen years numerous of the leading American universities have had organized departments to care for the health of their student bodies, the University of Minnesota made no provision to assume this responsibility until after the outbreak of the late war. Then with the establishment of a Reserve Officers Training Corps at the university, the United States Army provided medical service for students belonging to this training corps. The advantages to be derived from this medical service were so evident that arrangements were made by the university authorities to extend the service to all students of the university. In 1918 a beginning was made and the first staff, in reality an emergency one, was organized.

The first two years of this new organization were particularly trying ones. The war made it difficult to obtain sufficient and satisfactory medical service and the two years of influenza, which happened to come at this time, swamped even the most highly developed of medical institutions. The Students' Health Service, however, was able to weather the storm and since then has been rapidly developing into an efficient, scientific organization for the protection and conservation of the students' health.

PURPOSE

The purpose of the service, simply stated, is to assist each student to have and to enjoy the advantages of the best possible health. To accomplish this purpose, however, numerous lines of activity are necessary. Physical defects must be discovered and assistance given to the student in correcting them. Precautions must be taken to prevent the introduction and spread of communicable diseases. Medical advice and care must be made available so that students will seek care for diseases while they are still in their incipency; and the student body must be educated as to the value of periodic physical examinations and regular medical service.

CLINICAL STAFF

The staff of the Health Service for the current year consists of fourteen physicians, eleven den-

tists, ten graduate nurses, three dental assistants, one laboratory and x-ray technician, stenographers, clerks, etc. Of the physicians, six are on full time and eight on part time; of the dentists, one is on full time and ten on half time. The staff includes physicians well trained in internal medicine, diseases of the chest, surgery, ophthalmology and otolaryngology, physical therapy, gynecology, and dermatology and genito-urinary diseases. With such a staff consultations are frequent, and the advantages of group medicine are available to every student. The students are also encouraged to call in consultation at their own expense physicians not connected with the Health Service staff. In cases in which students cannot afford to pay or in which staff physicians desire consultation for their own satisfaction, the various clinical departments of the Medical School have generously given their services.

EQUIPMENT

The Health Service maintains two institutions, one on the main campus and one on the agricultural campus. The former is temporarily located on the ground floor of Pillsbury Hall. This location near the center of the campus is a happy one, but the building and the available space are far from satisfactory. It is hoped and expected that within a few years a new building will be erected for the Students' Health Service. This building, too, should be situated on the academic campus and as near to its center as is possible. The expense of maintaining a Health Service so situated will be greater than though it were included in the group of medical buildings, but the better service to the student body, due to its easy accessibility and to the fact that in it students are less apt to feel that they will be used for teaching purposes or be treated by medical students, will more than justify the additional expense.

At present in Pillsbury Hall a medical and a dental dispensary and an infirmary of twenty-five beds are maintained. In conjunction are an operating room, a laboratory, a small x-ray and fluoroscopic equipment, and a pharmacy. On the agricultural campus a separate building was assigned to the Students' Health Service and completely remodelled to suit its needs. In it we now have a very satisfactory out-patient dispensary and a hospital of forty beds, most of them in small rooms.

PHYSICAL EXAMINATIONS

The beginning of the physical examination of freshmen students at the University of Minnesota is deserving of special mention. Years ago, with little or no encouragement and with no assistance, Dr. L. J. Cooke, of the department of physical education for men, began to examine freshmen. His other duties were more than sufficient to occupy his time, but believing in the importance of physical examinations he kept at them and during the year personally examined each one of the freshmen men. From this beginning the progress has been gradual until now every student entering the University or the University High School must have as part of the requirements for matriculation a physical examination. If a student first enters the University High School, a second examination is required when he enters the university proper. An additional examination is required of those students who enter the medical school and another is given at the beginning of the third year in medicine. Furthermore all athletes who compete in intercollegiate sports are required to have an examination at the beginning of each season, and every student who desires a locker in the gymnasium must have a medical inspection and an examination if his previous record shows any indication for it.

These physical examinations are extremely exhaustive, comprising, in addition to a careful history of past illnesses, complaints and family tendencies, blood pressure readings, reclining and standing; pulse rate before and after exercise; vital capacity; height, weight and chest circumference measurements; general orthopedic inspection; examination for hernias, goiters, venereal disease, etc.; visual and hearing tests; eye, ear, nose and throat examinations; physical examination of heart and lungs; dental examinations; urinalyses; Schick tests; nose and throat cultures; Dr. Larson's precipitin test for tuberculosis—the so-called "ring test"; and smallpox vaccination of all students who need vaccination and who do not flatly refuse it. Upon the completion of an examination one of the members of the staff sums up for the student the findings recorded, advises him as to any medical or dental care that he needs and gives him a classification on the basis of his physical condition. A card index is then made of those students who showed any of the more serious defects and during the year these students are called

back for re-examination. A discussion of the results of these examinations would be interesting, but space will not permit of it at this time.

MEDICAL AND DENTAL SERVICE

The Health Service maintains an out-patient dispensary for students at which one or more physicians are in attendance at all hours of the day.

**DISPENSARY VISITS ON MAIN CAMPUS
PER 1000 REGISTRATION OF COLLEGIATE GRADE**

To this dispensary students are encouraged to come upon the first appearance of symptoms of illness, the prevention of disease being the primary purpose of the service. The student who comes to the dispensary is examined, given immediate treatment if any is indicated, and advised as to what he should do. If his condition indicates that he should remain in bed, he is directed either to go home to bed and call his family physician or to enter the students' infirmary. At the infirmary the student is cared for until he can return to classes, or, if his illness happens to be a prolonged one, until he can be removed to his home or to a private hospital. A student who becomes ill at his room will be visited once by a physician from the Health Service, but for prolonged treatment it is necessary that he enter the infirmary or call a private physician.

A dental clinic of six chairs was recently added

to the Health Service dispensary. Here dental examination, prophylaxis and reparative work are made so easily available that no student should neglect his teeth.

During the school year 1922-23 students made 35,654 visits to the Health Service dispensary (of these probably ninety per cent would never have reached a physician in private practice); 861 students were admitted to the infirmary and stayed on the average just 3.7 days; 578 calls were made upon students at their rooms; and 6,233 visits were made by students to the dental clinic.

THE CONTROL OF COMMUNICABLE DISEASE

In universities located in large cities and having a large percentage of their students living at home, as is the situation with the University of Minnesota, the control of communicable diseases is extremely difficult. Many precautions, which would be unnecessary were the university an isolated community, must be served. In general the routine is as follows: (1) the careful examination for communicable diseases of all students who come to the Health Service dispensary; (2) isolation of all students with symptoms suggestive of a contagious disease; (3) quarantine of all cases or suspected cases of contagious diseases; (4) daily observation or isolation of close contacts; and (5) inspection of all students who have been absent from classes on account of illness and wish to obtain excuses for the time missed. By this last precaution alone we were able during the past year to identify and exclude from classes one case of open pulmonary tuberculosis; two cases of smallpox; one case of diphtheria; one case of scarlet fever; numerous cases of acute follicular tonsillitis, etc.

POLICIES

The policies which are followed by the Students' Health Service have been formulated to provide for the students the best possible health supervision; to make available to them adequate dental care; to teach them to seek medical care whenever such care is advisable; and to interfere as little as possible with the private practice of physicians in the vicinity of the university. The prevention of diseases, the correction of defects, and the practical health education of the student body, are the paramount aims of the service. To make possible the accomplishment of these aims, however, a certain amount of general and specialized treatment of

disease is necessary. Students must have confidence in the institution and learn that it has a service to render them; otherwise they will not seek its advice at the time most important for the prevention of disease.

Upon the completion of his physical examination, each student is instructed as to any defects or abnormalities which are discovered and advised to seek the necessary medical or dental care. Each year, as a result of this advice, many students go to practicing physicians for further examinations or for treatment. Others who are working their way through school or who live away from

**HOSPITAL PATIENTS
PER 1000 DISPENSARY VISITS**

the Twin Cities return to the Health Service for further care. During the school year students who visit the Health Service dispensary are examined and advised as to their conditions. If they live in the Twin Cities and need further care, they are advised to return to their homes and call their family physicians. If a student needs an operation, other than an emergency, and can afford to do so, he is advised to go to a private hospital and call a private physician. Students with prolonged illnesses who are admitted to the infirmary are transferred to their homes or to a private hospital as soon as their conditions permit. By observing

these policies it has been possible to gain the confidence and support of the student body without infringing upon the physicians in private practice.

MAINTENANCE

As part of his tuition each student pays a health fee of two dollars per quarter, six dollars for the school year. From these fees sufficient funds ac-

**HOSPITAL DAYS, MAIN CAMPUS,
PER 1000 DISPENSARY VISITS.**

crue to pay the salaries of the staff, exclusive of dentists, and to cover most of the basic supplies and equipment. Students who receive services that entail extra expense to the institution are expected to pay on a cost basis for such services; for example, a charge for board and laundry of two dollars per day after two days is made to students confined to the infirmary; drugs are dispensed on a cost basis; x-rays are charged at cost and an operating room fee of ten dollars is charged for a major operation and one of five dollars for a minor operation. These charges are made to all students who receive such services, but a special provision makes it possible for the dean of student affairs to cancel the bills of especially deserving and needy students.

The dental department is required to be entirely self-supporting. To do this the charges for dental work are adjusted so that they will just cover salaries, materials, supplies, and depreciation on equipment.

ACCOMPLISHMENTS

It is frequently difficult to affirm with certainty that a particular form of treatment was responsible for a patient's recovery or that a certain preventive measure brought about the decline of an epidemic. Similarly in such work as the Health Service is carrying on it is difficult to measure accomplishments accurately. Before the establishment of the Health Service there was no accounting made of time lost because of illness nor was any record kept of even the serious illnesses among the student body, so nothing is at hand with which to compare present figures. A rough general comparison, however, can be made of the five years during which the Health Service has been in operation by comparing the following charts.

These charts show a progressive increase in the use which students are making of the dispensary and a corresponding decrease in the percentage of these who are sick enough to be sent to the infirmary. The decrease in the ratio of hospital days to dispensary patients is also significant.

Such figures as these can show definite accomplishments but they can never tell the whole story. The number of boys and girls who, except for the protection afforded, would have contracted communicable diseases, the amount of invalidism prevented by discovering chronic diseases in their incipency, and the lives saved by prompt medical surgical treatment will never be known and cannot be estimated. But even if we could have all of these accomplishments carefully itemized and tabulated we would still not have reached a sum total of the results of the work. One of the most important phases of the work would still have been overlooked. That is the educational phase. Certainly practical health education is one of the greatest opportunities of the service and one which is constantly emphasized. These thousands of students, most of whom have never before had a physical examination, are shown the value and the importance of periodic physical examinations and are taught to appreciate and to seek medical service whenever they become ill. They are vaccinated against smallpox and given Schick tests and they learn the value of these preventive measures as they would never learn them from formal instruction. The results which will accrue from such phases of the work one can never measure but every observer is convinced that they will be even greater and more far-reaching than the immediate and more tangible accomplishments.

PRESIDENTIAL ADDRESS

Minnesota State Sanitary Conference

November 2, 1923

GEORGE S. WATTAM, M.D.

Warren, Minnesota

In being permitted to address you today in the rôle of your presiding officer, I feel that I am accorded an unusual privilege and an honor most sincerely appreciated.

In accepting this trust at your hands, I assume the responsibility and the difficult task of endeavoring to contribute something that may be of interest and of value to those in attendance, and, through you, benefit the cause that we represent; but I promise not to weary you by a lengthy discourse, nor by quoting of tiresome statistics. The office of the State Board of Health, in an untiring effort to make this meeting a success, among other things, has provided, in concise form, a sheet giving statistics which I wish to commend to you for thoughtful perusal. It is worthy of careful analysis.

Many of you coming here to participate in this work do so at a sacrifice that can only be recompensed by the personal satisfaction of feeling that you are adding something to the welfare of your fellow citizens in assisting in solving some of the problems of modern sanitation; and, in behalf of the State Board of Health and the officers of this conference, I welcome you and your co-operation in the business of this session.

At this time we are in the midst of a financial distress and a mental unrest that history tells us is a logical sequence of all great wars; and when we try to give serious thought to estimating the huge loss of life, the destruction of property, and unreckoned misery which years of turmoil in Europe brought to the whole world, we are lost in wondering how so much of happiness and well being could have been preserved to the citizens of these United States. "Every cloud has a silver lining," and while we cannot replace the inanimate wealth so recklessly destroyed, nor the millions of lives so wantonly sacrificed, yet we have this consoling thought: Out of the chaos emerged a wealth of sanitary knowledge and a manifold increasing interest in all problems relating to health and the preservation of life.

We can, therefore, while reviewing with satisfaction the results of past endeavors to curtail disease,

look hopefully into the future for brighter prospects of attaining to the ideal. New agencies for the sale of sanitary knowledge are in the field, inspired on the one hand by a greater interest man now has in the welfare of his fellow man, and on the other by undeniable evidence that freedom from disease is an essential factor in material prosperity.

"Ill fares the land, to hastening ills a prey, where wealth accumulates and men decay." Influenced by the spirit of this thought of Goldsmith in the eighteenth century, our great employers of labor, controllers of wealth, are recognizing that accident and disease take an enormous unnecessary toll, and that it is cheaper to prevent than to cure.

The great insurance companies, powerful manufacturing corporations, believing it to be a good investment, are freely giving thought and money to modern sanitation, and our nation and state are appropriating, in increasing amounts, to assist in combating unnecessary disease. That most splendid and beneficent organization of historical mention, the American Red Cross, seeking new fields for its various activities following the recent war, turned a portion of its powerful influence for good into the hopper of better health. Churches, fraternal and business organizations, too numerous to mention, are all lending a helping hand, and it is an inspiration for all engaged in this cause to know that health work done in the past has not been in vain. In fact, if we but recall the havoc that communicable disease has caused in the past, we have every reason to view the future with optimism.

The Metropolitan Life Insurance Company tells us that a lessened death rate since 1911 saved that company nearly twelve million dollars in the year 1922; and we are also told that in the past thirty years twelve years has been added to the life of civilized man by modern methods of disease prevention.

Typhus fever, yellow fever and cholera, that from time to time scourged these United States, have been banished for good, and bubonic plague has never been able to gain a foothold in this country. Malaria and hookworm, so recently strong factors in causing ill health and poverty, are facing extermination.

Turning to our own State of Minnesota, we have every reason to be proud of the record made by our State Board of Health and its official and non-official auxiliaries.

Our State Board of Health, beginning its work

in 1872 on a petty sum of \$500.00, is now receiving an annual appropriation of \$145,500.00, or two hundred and ninety-one times the amount allotted for this splendid purpose at its inception some fifty years ago. In addition to this, the state and county sanatoria for the care of patients having tuberculosis are costing the State of Minnesota \$242,000.00 annually, making a gross amount of \$387,500.00. This appears like a very large sum to many members of our state legislature when we appeal to them once in two years for necessary financial assistance. Indeed, it is a large sum of money, and we may well ask: Is Minnesota justified in making this expenditure? Let us see!

The Division of Vital Statistics of the State Board of Health tells us that had the same death rate prevailed in 1922 that did in 1871, we would have had 5,538 more deaths in 1922 from five diseases, viz.: smallpox, tuberculosis, scarlet fever, diphtheria and typhoid. A saving of 5,538 lives in one year in only five diseases. Estimating the value of each human life saved at \$100.00, or the price of a fairly good cow, and at the end of the year we have returned to the State its \$387,500.00 and interest at 42 per cent. A pretty good investment! But if to this we shall add the saving of a decreased death rate from pneumonia, measles, whooping cough, diarrhea and other preventable diseases of childhood and youth, we will probably have saved a sum nearly equal to above amount, which is all "pure velvet." In addition we should add the cost of care of the sick, loss of time, and expense of burial—a mathematical problem that I have not had the time to solve. Yes, a saving of probably more than 10,000 lives annually to the State at an increased tax burden of fifteen and one-half cents per capita (one dish of ice cream for each). However, there is little need to consider this question from the standpoint of financial expediency.

The suffering and poverty engendered by disease

appeal so forcibly to our better natures that the cost of remedial measures becomes a secondary consideration, while the interest man now has in the welfare of his fellow man is sufficient incentive for welfare work that is seeking the subjection of preventable disease.

That we have not yet reached the limit of possibilities for the prevention of disease is being constantly demonstrated. A striking example of what may be accomplished has been recently shown by the Metropolitan Life Insurance Company at Thetford Mines, in Canada, where, beginning in 1921, by a systematic and well-planned campaign by a staff of nurses to lessen infant mortality, the death rate for infants was lowered over 50 per cent in two years.

Notwithstanding all that has been accomplished, it is estimated that the loss from preventable disease in the United States still reaches the enormous total of three billion dollars annually, while that from lost wages due to illness alone is greater than the total value of the wheat crop of this country. So there is plenty of work left and need for self-sacrifice on the part of all who feel that they may lend a helping hand to save a brother or a neighbor from impending danger, and in thus helping others, incidentally help themselves.

That the death rate from tuberculosis in this state is now only slightly more than one-half; of infants under one year about two-fifths; that from diphtheria only one-third; from scarlet fever only one-sixth; and typhoid fever about one-twenty-eighth that of a few years ago is surely enough reward for the few hours spent each month by volunteers enlisted in the work of public health and sanitation in Minnesota.

So we gather here today to pledge our aid in this good cause, sharing one with another and with the splendid pioneers of bygone days the credit of having made Minnesota one of the healthiest states of this Union.

APPARENT DEFORMITIES OF THE PILLARS OF THE FAUCES, SEEN AFTER AN IDEAL TONSILLECTOMY*

F. J. PRATT, M.D., F.A.C.S.

Assistant Professor of Ophthalmology and
Oto-Laryngology, Medical School,
University of Minnesota

Minneapolis

This paper deals only with throats that have had tonsillectomies where no muscle tissue has been removed.

The cause of apparent deformities in the pillars of the fauces is due to anatomical variations in their structure.

"The palato-glossus is a small, fleshy fasciculus, narrower in the middle than at either extremity, forming, with the mucous membrane covering its surface, the anterior pillar of the soft palate. It arises from the anterior surface of the soft palate on each side of the uvula, and, passing downwards, forwards and outwards in front of the tonsil, is inserted into the side and dorsum of the tongue, where it blends with the fibres of the stylo-glossus muscle. In the soft palate, the fibres of this muscle are continuous with those of the muscle of the opposite side.

Fig. 1. Normal pillars.

The palato-pharyngeus is a long, fleshy fasciculus, narrower in the middle than at either extremity, forming, with the mucous membrane covering its surface, the posterior pillar of the soft palate. It arises from the soft palate by an expanded fas-

ciculus, which is divided into two parts by the levator palati. The anterior fasciculus, the thicker, lies in the soft palate between the levator and tensor, and joins in the middle line the corresponding

Fig. 2. Muscles of the pillars.

part of the opposite muscle. The posterior fasciculus lies in contact with the mucous membrane, and also joins with the corresponding muscle in the middle line, passing outwards and downwards behind the tonsil. The palato-pharyngeus joins the stylo-pharyngeus, and is inserted with that muscle into the posterior border of the thyroid cartilage, some of its fibres being lost on the side of the pharynx, and others passing across the middle line posteriorly, to decussate with the muscle of the opposite side."

Fig. 3. Muscles of the Posterior pillars from behind.

An ideal throat has large muscular pillars, the anterior pillars about one-third the size of the posterior pillars.

*Presented before the annual meeting of Minnesota State Medical Association, St. Paul, October, 1923.

The variations are as follows:

1. Large muscular posterior pillars and thin anterior pillars. This is the most common variation. (Fig. 4.)

Fig. 4

2. Large muscular anterior pillars and small posterior pillars. The anterior pillars stand out well; the small posterior behind the anterior, at first glance, look as though they had been removed. (Fig. 5.)

3. A large muscular posterior pillar and a thin anterior pillar on one side and a large muscular anterior pillar and a thin posterior pillar on the other. (Fig. 6.)

Fig. 5

4. Fairly large anterior and posterior pillars, but the posterior pillars one-third to one-half way

down blend into the muscular wall of the pharynx. (Fig. 7.)

5. The pillars on one side normal, but on the other side the posterior pillar one-third to one-half way down blends into the muscular wall of the pharynx. (Fig. 8.)

6. Both anterior and posterior pillars narrow and contain a small amount of muscle tissue. (Fig. 9.)

7. The pillars on one side normal, but on the other side the posterior pillar comes off high up behind the anterior pillar. (Fig. 10.)

The ideal pillars are generally found in the patients with large throats and tonsils of medium size.

The pillars in the throats of patients with large tonsils tend to be small; whether the large tonsils cause small pillars, or small pillars large tonsils, I am unable to say.

Fig. 6

Thin pillars or pillars with small amount of muscle tissue tend to collapse after a tonsillectomy, as there is not enough muscle tissue to hold them out, but plainly show if the patient gags.

A careful examination of a throat before a tonsillectomy will tell you just the kind of a throat to expect after a tonsillectomy, providing the muscle tissue has not been injured during the operation.

DISCUSSION

WILLIAM R. MURRAY, Minneapolis: The anatomical description of the muscles which form the faucial pillars and the illustrations shown by Dr. Pratt demonstrate very nicely the variations which may occur in these structures, and when these anatomical differences exist, we expect to get a

somewhat different post-operative appearance in the fauces after tonsillectomy than we would have if the muscular structures composing the pillars were of the usual development and symmetrical on both sides of the fauces.

Fig. 7

I believe that these differences in the muscular development are more apparent than real in so far as they affect the ultimate appearance of the fauces after a tonsillectomy, and the appearance of the pillars and fauces immediately after operation is not always an indication of the ultimate appearance six months after operation.

There are other anatomical factors that influence the post-operative results of tonsillectomy. The sinus tonsillar is may be exceedingly deep and may extend high up into the soft palati above the junction of the anterior and posterior pillars and the upper lobe of one tonsil may extend

Fig. 8

much higher than the upper lobe of the opposite tonsil, in which case there is an asymmetry in the appearance of the pillars immediately after operation. This, however, is not

a deformity and later after the healing process is complete this asymmetry usually disappears.

Sometimes the anterior and posterior pillars are adherent to the tonsils so that in separating them from the tonsil a denuded surface is present on the posterior surface of the anterior pillar and the anterior surface of the posterior pillar. During the healing process the anterior and posterior pillars become drawn together and in some cases almost obliterated. This does not necessarily mean a deformity and gives no unfavorable results other than a temporary feeling of tenseness or drawing sensation which disappears.

The extent to which the external surface of the tonsil is attached to the muscular bed of the fossa may influence to an extent the post-operative appearance of the fauces. Usually the upper half of the tonsil is very loosely attached to the sinus tonsillar. The area to which the tonsil is firmly attached to the fossa varies greatly and sometimes extends to the borders of the anterior and posterior pillars. In these cases there will be greater obliteration of the fossa and pillars following the healing of the wound.

The presence of a well developed plica triangularis may influence the post-operative appearance, as the plica is removed with the tonsil.

Fig. 9

The immediate, and sometimes the final, post-operative appearance, then, may be influenced by anatomical and pathological conditions that may be present previous to operation and the so-called apparent deformities referred to by Dr. Pratt are not deformities, and cause no unfavorable symptoms, if no operative injury has been done to surrounding muscle tissue.

DR. CARL L. LARSEN, St. Paul: I am pleased that Dr. Pratt used the word apparent because a great many of the deformities are more apparent than real.

While a perfectly performed operation is our aim and undoubtedly leaves the most ideal throat, I am convinced that there are many exceptions.

If the sinus tonsillar is deep and the tonsillar root extensive, the surface denuded by the removal of the tonsil

will include nearly the whole of the sinus even to the edge of the pillars. Here contraction of the cicatrix may pull the pillars so closely together that they appear to be and often are adherent.

There is actually no deformity but the pillars do not stand out with a distinct gutter between them, which is the ideal end result.

Fig. 10

Difference in the size of the tonsils, difference in the attachment, the arch of the palate or the tonsils being higher on one side than on the other, are conditions that frequently account for the difference in appearances of the

two sides and consequent asymmetry which is not the ideal looking throat.

Infection, too, plays an important part. The more infection the greater the cicatricial contraction and the greater tendency to agglutination of the denuded surfaces.

I am convinced that after tonsillectomy nothing should be done to interfere with nature's attempt at repair. I doubt the efficacy of gargles; they do no good, are often painful and frequently interfere with prompt healing.

I do not believe we can always tell beforehand just what kind of a throat we are going to have following tonsillectomy. The separation of the anterior pillar by sharp dissection with knife, scissors or Sluder, the remaining dissection and removal of the tonsil with a minimum amount of traumatism is undoubtedly the ideal operation, but unfortunately, no matter how skillfully performed, the ideal looking throat is not always attained.

DR. F. J. PRATT, Minneapolis (closing): It is impossible to tell exactly what kind of throat you are going to get because some people scar more than others, and naturally there will be more contraction. What I meant was that we can get an idea of about the kind of throat we are going to have by the amount of muscle tissue there is in the pillars. The thing that brought this paper to my mind was: Why was it that after doing a tonsillectomy apparently the same way every time, the throats were not all ideal? Some had what we call nice normal throats and others had not. That led me to make a study of these cases, and I have been keeping track of them for a number of years. I have seen all these different variations, and I came to the conclusion that they were anatomical. There have been plenty of papers on deformities of the throat but nothing has been said about anatomical variations.

Periodic Health Examinations

The human body is a wonderful machine, but how woefully mistreated through carelessness and ignorance. There were times when a man would deliberately mutilate his body in the name of religion. Ideas, fortunately, have changed. It is being more and more realized that a healthy body is more likely to result in a better functioning brain and a happier individual.

The Britisher holds his athletic games indispensable. Such Americans as Roosevelt, Taft and Coolidge have realized the necessity of taking time out of a crowded day for attention to physical needs. Cyrus Curtis of Curtis Publishing Company fame is a good example of a busy man not realizing the importance of taking care of himself until he was turned down for life insurance some twenty years ago. He is also a good example of

how life may be extended and be made even more efficient by devoting a little attention to bodily needs.

The purpose of periodic health examinations is not only to discover signs of early disease, which may be amenable to treatment, but to detect errors in habits, which are either interfering with good health or are likely to cause trouble in the future. A business man was once heard to remark that in his opinion if the average young man was not a success at his occupation, whatever it might be, there was generally some bad habit to account for it. This is the sort of thing that a periodic health examination should ferret out and it is apparent that such an examination must of necessity be quite different from the ordinary consultation. It is quite evident that the idea of such examinations must be sold to the profession if they are to amount to anything. Perhaps the best way of convincing any "doubting Thomas" would be to have him make such examinations. It would not be long before he would be impressed with the number of individuals with diseased tonsils, carious or abscessed teeth, whose chest and waist measurements should be reversed, or who are using coffee or tobacco to excess.

The examination of supposedly healthy individuals is not entirely new. It is a common saying that the Chinese physician is paid to keep his patient well. Infants in infant welfare stations, school children and college students on entering an institution, workers at industrial establishments, life insurance applicants and policyholders commonly go through a more or less thorough overhauling. Many unsuspected abnormal conditions have been detected by such examinations.

The present move for periodic examinations originated among the laity, which is as it should be. Numerous organizations, some supervised by non-professional men, have sprung up to satisfy and augment the demand. The Life Extension Institute of New York, headed by Dr. Eugene Lyman Fiske, is the largest and best known organization of this sort. Begun with a humanitarian motive, it has proven its worth in dollars and cents to many insurance companies and bids fair to continue its already rapid growth.

The National Health Council, composed of a number of nation-wide associations such as the Red Cross, Public Health Service, National Tubercu-

lois Association, Woman's Foundation for Health, et cetera, is carrying on a nation-wide campaign for health examinations and has adopted the slogan "Have a Health Examination on Your Birthday."

Realizing the growing demand for these examinations, our national organization gave the idea its approval at San Francisco last summer, and the Council on Health and Public Instruction of the American Medical Association has prepared an outline form for use by physicians. In the *A. M. A. Journal* of May 12, 1923, the form is thoroughly explained in an article by Dr. Haven Emerson. Reprints of this article and examination forms may be obtained from the *A. M. A.* headquarters.

It has been suggested that each county society take up the proposition of periodic health examinations at one of its meetings. A thorough discussion of the subject based on Dr. Emerson's report should clear the atmosphere. Whether public announcement that the local physicians are prepared to give these examinations is made or not should be left to each county society to decide.

It is unquestionably desirable to have some form to follow to insure a methodical and thorough examination. The work will be greatly facilitated if the applicant makes out his portion of the blank in advance of the physical examination, which should preferably be by appointment. The *A. M. A.* form insures thoroughness, which is fully as important in such examinations where there is often no clue offered to existing trouble as in ordinary consultations. Examinations of supposedly well individuals are, too, quite different in the matter of advice to be given regarding personal hygiene.

The medical advisor and particularly the general practitioner is the logical one to conduct these periodic health examinations. The examiner himself is in a far better position after personally examining and discussing the patient's habits to give valuable advice than anyone, even a medical man, in a distant city, providing, however, the examiner is in sympathy with the procedure and takes the trouble to give this sort of work the necessary thought.

The only reason these examinations are being carried on by anyone other than the family physician is because we have been slow to meet the situation. The demand exists. Are we as a profession going to meet it?

Doctor Amos W. Abbott—A Tribute

It is characteristic of every community to present certain outstanding figures. There is always to be found a minority who, because of special attributes, reach heights which are unattainable by the great majority of individuals. The medical profession is richly endowed with these outstanding figures. A favorable heritage plus a good fundamental education and an unceasing effort to obtain and apply knowledge are the essential assets which make it possible for certain individuals to achieve well-earned distinction.

Too often great men are unappreciated in their respective communities until after they have passed on. Too often, bouquets, both in a literal as well as a figurative sense, are withheld from those whose achievements merit the appreciation of those about them until they are no longer with us. Too often, do we fail to make known the fact that we are cognizant of the exceptional worth of outstanding personalities until after they have gone to their reward, when the knowledge of the esteem in which they were held can be transmitted to their survivors only.

Only occasionally does the realization of the honesty, integrity, character, personality and achievements of an individual present itself with such exceptional force to those who are familiar with his accomplishments that the offering of a befitting tribute is made while he is still among us and in a position to realize the esteem in which he is held by his confrères.

A delightful and unusual example of spontaneity in offering a well-deserved tribute took place at the Minneapolis Club on Saturday evening, March 1st, when an assemblage of about one hundred friends of Dr. Amos W. Abbott gathered to pay a tribute to this well-known surgeon upon the occasion of his fifty-fifth anniversary in the practice of medicine. At a dinner given in his honor his friends vied with each other in eulogizing him and showering him with felicitations. The fact that Dr. Abbott is still in possession of excellent health and virility with mental facilities as acute as those of the average man of fifty added zest to the occasion. His record in the Civil War, in which he took part while not yet of legal age, his achievements as a teacher in the medical school, his contributions to medical science, the indelible impression he has made upon the practice of medicine in the Northwest, his uni-

versal kindness, encouragement and direction of the younger members of the medical profession, and his loyalty as an American citizen, were dwelt upon by the speakers from various walks of life in a manner befitting his rank. Dr. Abbott and his family were made to realize the pinnacle upon which this nestor of medicine and surgery stands in this community.

With the modesty and diffidence which are characteristic of Dr. Abbott, he returned his thanks for the many words of appreciation offered by those present and in addition credited Mrs. Abbott and his faithful nurse, Miss Holmes, and others who have been associated with him, with being responsible for any success he might have attained. He further paid a glowing tribute to Messrs. O. C. Wyman, T. B. Janney and Wm. F. Dunwoody, the gentlemen who had so whole-heartedly donated large sums of money, thus making possible the establishment of the magnificent institution of which he is the head.

MINNESOTA MEDICINE and all of Dr. Abbott's acquaintances appreciate the fact that were it not for his remarkable achievements, his staunch and conscientious observance of the Golden Rule, combined with his sterling qualities and personality, these influential citizens would not have been inspired to donate so generously for such a worthy cause. We know that his example has been and will be a lesson to all other members of the medical profession and we hope that other citizens who are financially able to do so will see the necessity and righteousness of following the example of Messrs. Wyman, Janney and Dunwoody.

We take great pleasure in joining with Dr. Abbott's friends and admirers and adding our mite. Though not in measurable or tangible form—yet we would have him feel it is our sincerest wish to bestow upon him the greatest endowment within our power—our appreciation and love.

Minneapolis Health Exposition

In keeping with the idea that prevention of disease is far better than cure, the Hennepin County Medical Society will launch, from May 3 to 10, 1924, the first Health Exposition in this part of the country. Only five other cities have so far held such expositions. The medical society is the logical agency to manage such an activity, although numerous other civic and social organizations will take part.

The Exposition has chosen for its motto "Live a Little Longer." Education is the main factor in accomplishing this result. Prevention of unnecessary sickness, care of the sick, sanitation, ventilation, social science and kindred topics will be emphasized. There will be elaborate displays of all kinds, most of which will deal with medicine, surgery, dentistry, pharmacy, safety methods and other topics of interest to the general public. Lectures will be enlivened by entertainment features and motion pictures.

Eminent scientists from various parts of the country will be invited to Minneapolis for the week. The simultaneous holding of Minneapolis Clinic Week (May 6 to 9) should afford a double-header attraction for physicians and public alike.

COMMUNICATIONS

St. Paul, Minn.,
March 10, 1924.

TO THE EDITOR:

In compliance with our conversation of the other day, I am writing you as follows:

SIMPLE GOITER PREVENTION

Minnesota is in the goiter belt of North America. The prevention of simple goiter is of import to every person in the state and of special interest to the medical profession.

The story of the use of iodine as a preventative in the human has been most interestingly told by Marine and Kimball and the agricultural experiment stations of the Northwest have told the story in animal husbandry.

By addressing the Surgeon-General, United States Public Health Service, two interesting reports upon this subject may be obtained—the "Prevention of Goiter," Reprint No. 832 from the Public Health Reports, April 27th, 1923, and the Public Health Reports of January 11th, 1924.

We have for some time been trying to obtain some definite statistics as to the prevalence of simple goiter in Minnesota. Not being able to find any statistics already compiled, a survey was made of the sixth, seventh and eighth grades, corresponding to the ages of eleven to fifteen, of twenty-nine public schools in St. Paul.

We followed the classifications of Marine and Kimball of "Slightly enlarged, moderately enlarged and enlarged," slightly enlarged indicating the "palpable only" type. Our five medical inspectors were sent out to make this survey, one man doing a school with a nurse assisting. The findings were so startling that we had other medical inspectors go over the same schools to verify the results (they were not previously notified that the building had been surveyed). The second survey confirmed that of the first, the greatest difference being only five per cent.

Twenty-nine grade schools and two high schools were surveyed, the average findings being as follows:

GRADE SCHOOLS

	Number examined	With enlarged thyroid
Girls	2,608	73%
Boys	2,559	54%

CLASSIFIED AS TO DEGREE OF ENLARGEMENT

	Girls	Boys
Slightly enlarged	41%	45%
Moderately enlarged	26%	11%
Enlarged	6%	2%

These figures seemed so astounding to us that we were in doubt whether to believe them. Of course, this classification is of gross character, but nevertheless valuable. As Marine and Kimball state, about 75 per cent respond to prophylactic iodine treatment.

HIGH SCHOOLS

In Humboldt High School, in a group of 235 girls, 73 per cent had enlargement and in a group of 150 boys, 58 per cent had enlargement.

In Central High School, in a group of 134 freshman girls, 78 per cent had enlargement and in 127 freshman boys, 45 per cent had enlargement.

CLASSIFIED AS TO DEGREE OF ENLARGEMENT

	Girls	Boys
Slightly enlarged	39%	44%
Moderately enlarged	34%	1%
Enlarged	5%	0

Second in point of interest to the large average percentage of enlargement of the thyroid, is the variable distribution throughout our city. For instance, in our First Ward, the average incidence in girls is about 90 per cent; in the Eighth Ward the school average is 51 per cent; in a school in the Tenth Ward 47 per cent and another school in the Tenth Ward 46 per cent. There were many other variations in distributions of this character and a study is being attempted to analyze these differences. It is to be remembered that the same physician surveying a high percentage school also reported low percentage schools.

OTHER CITIES

We were able lately to obtain a compilation from the Minnesota State Board of Health of surveys made in five of the smaller cities, namely, Eveleth, Gilbert, Hibbing, Grand Marais and St. Peter. The total findings were as follows:

Girls with enlarged thyroid.....	70.4%
Boys with enlarged thyroid.....	42.6%

In one place children below the age of ten years were surveyed and, of course, this brought down the total average.

CAUSES

The great variation in the prevalence of goiter in different districts of the city is difficult to analyze. The economic

conditions are a factor, as well as the national food habits and the local environment.

We believe that diet is the principal factor. In the First Ward, we have a Swedish population that is extremely local in its habits. For several generations they have lived in this locality. The food habits have changed since leaving the Scandinavian peninsula. Our investigation shows that the principal diet consists of coffee, bread, cake, meat and potatoes. These foods lack the iodine content and may be one reason why they have a large percentage of thyroid enlargement.

In districts where economic conditions prohibit the purchase of vegetables throughout the year, and where the districts are so congested that gardens are not grown, we also find a large percentage of thyroid enlargement.

In other districts where economic conditions are not so severe and a larger amount of southern grown vegetables are purchased with a large iodine content, we find less enlargement of the thyroid.

The possibility of atmospheric iodine must be considered. McClendon states that the burning of coal disseminates iodine in the atmosphere.

FUNCTION OF IODINE

Marine explains the physiological action of iodine as follows: "Starting with the normal thyroid there is a decrease in the iodine store and a corresponding decrease in the stainable colloid. If the iodine store falls below 1 mg. per gram of dried gland, active hyperplasia begins. If the iodine deficiency is not met, the thyroid glands will go on to cellular degeneration and atrophy, or where the iodine deficiency is met, it returns to the colloid or resting stage. This is the nearest to normal that an active hyperplastic gland can come and function normally.

"Experiments show that the thyroid will start to enlarge as soon as the iodine content gets below one-tenth of one per cent of the total amount of dried gland tissue. When the iodine content of the thyroid gland in pregnant animals is deficient, the young are born with goiters, while on the other hand this tendency toward goiter formation in the young could be prevented by maintaining a normal iodine content in the mother's thyroid. (1) Iodine is necessary for the normal function. (2) The iodine content varies inversely with the degree of hyperplasia. (3) The percentage of iodine present in individual thyroids is variable, but there is quite constant minimum percentage which is necessary for the maintenance of normal or colloid gland structure. If the iodine content falls below one-tenth of one per cent, active hyperplasia begins. Also, iodine is necessary for the physiological activity of the thyroid secretion."

Simple goiter or the simple enlargement of the thyroid gland is common in certain portions of the globe. The knowledge of the simplicity with which the majority of thyroid disarrangements could be prevented is so important that everybody must know what to do and how it must be done.

Goiter is one of the most insidious diseases which attack man and animals and the easiest to prevent.

Under the classification of simple goiter, we now include all those thyroid enlargements in man and animals which were formerly designated as endemic, epidemic, sporadic and physiologic or adolescent goiter.

Practically all of the preventive work has been confined to the adolescent age. There is little, if any, danger of aggravating toxic thyroid types with the small amount of iodine administered.

It must be remembered that the purpose of the administration of iodine among the adolescent is for prevention and not treatment. Those having a thyroid that requires treatment should place themselves in charge of a physician. We do not believe in advising adults to take iodine for enlarged thyroid unless they are under observation of a physician.

WATER SUPPLY

Iodizing the water is an expensive procedure, due to the large amount of city water supply for other than drinking purposes. There is a possibility of iodized water aggravating the toxic goiter; there is also the danger of iodized water interfering with certain commercial enterprises,—such as bakeries, laundries, etc.; in some places this fact has caused considerable opposition.

The States of Wisconsin, Montana and Michigan, through their agricultural departments, issue a vast amount of printed matter for the prevention of thyroid difficulties in fish and livestock. These publications are usually issued under the title of "Hairlessness" and "Goiter" or "Hairless Animals."

Early in 1918, in Switzerland, long known to be the most goitrous country in the world, a campaign to eradicate goiter was begun in the schools of Zurich under the direction of Dr. R. Klinger. It was found that in some of the schools 100 per cent of the children were goitrous.

The governing authorities of the different cantons of Switzerland realized how readily and easily the incidence of goiter could be controlled. Measures were adopted for an energetic campaign to stamp goiter out of the country. The Canton of St. Gall, Berne and Zurich have for more than three years given treatment to the school children with striking results. The figures show that before the treatment was inaugurated goiter occurred in 61 to 97 per cent of all children. After treatment, the percentage had fallen to 27.5 per cent.

CONCLUSIONS

1. The importance of local surveys in Minnesota has been shown and more should be made.
2. Enlarged thyroid is prevalent among the adolescent and radical steps towards its prevention should be taken at once.
3. The most practical and effective method is the weekly administering by mouth of small quantities of iodine preparations.
4. Simple goiter is easy of diagnosis and is the easiest known disease to prevent.

Very truly yours,

E. A. MEYERDING, M.D.,
Director of Hygiene.

La Crosse, Wis., Feb. 9, 1924.

MINNESOTA MEDICINE,
Gentlemen:

Have read with much interest your editorial concerning the optometrists and their professional standards, reprinted in the *Optometric Weekly*. The editorial is well handled. But it reminds me of the Minnesota Swede that poked fun at the Wisconsin German because the Wisconsin German spoke broken English, and we laughed at the broken English of the Swede, and he got mad.

Reform should begin in one's home before we attempt to go into the world and reform the world. The Jew says that the Golden Rule is a good rule and ought to be obeyed, but he is a Jew and does not believe in Christ.

If I interpreted the editorial, the mind that wrote it had the purpose of having us believe that *the* mind was one mind in authority.

When the editorial was written the writer did not have before him the fact and truth that physicians and surgeons, with the title M.D. added, run cards in their local papers that read like the ones I have inclosed. So may we ask, if it is these men that the editorial refers to when it speaks of the medical oculist. Are these physicians oculists?

Suppose members of the medical profession began in their own ranks and reformed themselves and made it impossible for any doctor with the title M.D. to assume the title oculist until he had earned that which you propose the optometrist should earn before he examines eyes and fits glasses.

Is not the correspondence between the physician and the editor of a medical journal significant as it relates to the reform that you have proposed for another? Of course many laymen do not know that such things exist among the medical profession.

Nearly every country doctor of medicine has a trial case today, and when he cannot find a surgical job he gets out the trial case and sells them glasses. Ask any oculist what he thinks of it.

The right to confer the title doctor rests with the people. A charter is granted any college to confer its titles by the people. People have addressed me as "doctor" for years and years, and only lately have I begun to use it in my advertising. And everyone believes in advertising. Did you ever know of a doctor of medicine that refused to permit all the free advertising that he could get, that would help him become a Will or Charles Mayo?

The optometrist will be faithful to the people who employ him or the people will destroy the optometrist. No other organization can destroy the optometrist who does not practice medicine, and the courts of the country, that we honor, have rendered a decision that any man, doctor of medicine or otherwise, who examines eyes and fits glasses is not practicing medicine.

When I cannot produce normal vision for a person, I recommend that he go to his family physician, and when I note diseases of any kind I recommend that the person go to his family doctor. Then what happens in lots of cases? The person has listened to the family physician recommend that when the person gets his eyes fitted to glasses, he should go to the oculist and not back to the

optometrist. And the Jew says the Golden Rule is a good rule for Christians, but he is a Jew.

If an optometrist makes a mistake it is different than when a doctor of medicine makes a mistake.

The writer has been examining eyes and fitting glasses for over twenty years, and I offer and do refund money when I fail. Ever hear of a doctor of medicine refunding money when he fails? And I am just an ordinary optometrist, because I have not a good press agent or the money to hire one, but the people, whom I have learned to trust, will cleave to that which is right.

I hope that the doctors of medicine will read what is printed in the editorial and apply it to themselves, and I am glad the optometrists have the same privilege.

Very truly yours,

H. CLAY EVENSON.

P. S.—I know one of the finest surgeons of our city, who will fit you with glasses, and he does not assume the title oculist.

Editor's note: The editorial referred to appeared in the October, 1923, number of MINNESOTA MEDICINE. It is not our purpose to enter into a debate on this subject, but the above viewpoint of an optometrist is interesting and hits some vulnerable spots in the medical profession. For anyone to hold that all M.D.s are beyond criticism and all optometrists inefficient would be absurd. What is more, it is doubtless true that a well trained optometrist can fit a pair of glasses better than the average M.D. at graduation. There can be no argument, however, on the point that the medical graduate has a firmer foundation to build upon than the optometrist.

Obviously the weak link in our present stand in the matter of fitting glasses is the casual sort of work done by some of our regular doctors. Even at that, however, no one could say that a lot of jewelers and bungling opticians should be allowed to fit glasses, chiefly in order to sell them.

If the development of optometry were the result of a demand for a specialist in fitting glasses in a sparsely settled district where the M.D. was more occupied in the pursuit of the various other medical activities, we might feel differently about the situation. On the contrary, optometry has developed for the most part in the thickly settled districts where there is no paucity of oculists. The rank and file of optometrists advertise; the advertising oculist is the exception and as a rule is classed by his fellow practitioners as an outsider. Doubtless some M.D.s have felt forced to advertise by the advent of numerous advertising "specialists," just as the allies were forced to take up gas warfare, although not approving of it.

As intimated in the editorial, the optometrist is developing a professional sense but the medical profession has a twenty years' lead over the present optometrists. If the optometrists are in dead earnest, let them acquire all the current knowledge in existence pertaining to all phases of science having to do with the life work they have chosen. The public demands thorough education for those entrusted with the care of the teeth. Surely our eyes are fully as valuable as our teeth.

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

MINNEAPOLIS CLINIC WEEK—1924

The days for Minneapolis Clinic Week are May 6, 7, 8 and 9.

The first two days, May 6 and 7, will be devoted to *dry clinics* entirely. The following days, May 8 and 9, will be devoted to clinics at hospitals where perhaps some of the patients that are exhibited at the dry clinics will be operated in the wet clinics; or medical cases which are shown there will be demonstrated later perhaps by more suitable methods.

There has been some question as to the meaning of "dry clinics," and the plan of the Committee in charge is to have the entire attendance congregated in one meeting place (that to be selected later) where all the men may see the ambulatory or bed clinics that will be given on a raised platform and will be demonstrated by men who have been chosen for this special line of work. We do this with the expectation that many may get more from a dry clinic under these circumstances than a few may get from an operative or bedside clinic at a hospital.

Any man from outside the Twin Cities may send in his patient for a dry clinic demonstration if he so chooses.

Minneapolis Clinic Week is to be closely affiliated with the Minneapolis Health Exposition which will be in operation from May 3-12 at the Armory Building in Minneapolis, and where several phases of public health work, educational work related to public health measures, and commercial exhibits which are related to both, will be carried on.

It is expected in the Health Exposition that a large number of men will participate in the demonstrations at the various booths and during the clinical examinations which are to be given at the same time.

The Annual Banquet given by the Hennepin County Medical Society will take place on the evening of Wednesday, May 7th, at the Radisson Hotel, which will also be the headquarters for Minneapolis Clinic Week.

UNIVERSITY SHORT COURSE

The attention of the profession is called to the change in the plans for the short courses in postgraduate work to be conducted by the University this summer.

This year the courses will be condensed to two weeks instead of four in the hope that a larger number will enroll and take the full course.

The course in Medicine and Surgery will run for two weeks beginning May 26, 1924. The date previously announced in a circular postal card has been advanced to May 26, so as not to interfere with the American Medical Association meeting in Chicago, which begins June 9.

The course in Pediatrics and Obstetrics will be held in September, 1924.

The University has conducted these courses for the past four summers for a period of four weeks in the month of May. The course has been a general one in the past and the average attendance has been about thirty. Shortening the course and dividing it in two will, it is hoped, prove more practical to those interested.

TRI-STATE DISTRICT MEDICAL ASSOCIATION

Interstate Post-Graduate Clinic Tour to Canada, British Isles, and Paris in 1925 is now being arranged under the supervision of the Managing Director's office of the Tri-State District Medical Association. The time for leaving will be about the middle of May.

The tour will consume, approximately, two months' time and the total cost from Chicago and back to Chicago again will be less than \$1,000.00. This will include all clinic arrangements and admissions and all traveling expenses, except meals on Pullmans in America and tips on the ocean steamer. First-class hotels will be used everywhere and the ocean passage will be on the largest and finest of the new one-cabin ships.

Clinics are being arranged in Dublin, Belfast, Liverpool, Manchester, Leeds, Edinburgh, Glasgow, Newcastle, London and Paris and other points of clinical interest. The clinics will be conducted by the leading clinicians of these cities. The opportunity will be given, subsequently, to visit the clinic centers in other parts of Europe.

This tour is open to members of the profession who are in good standing in their state or provincial societies and their families and friends.

Sight-seeing programs will be arranged practically every day abroad, including the most scenic part of the countries visited, without extra cost.

On account of the great demand for reservations, applications should be made as early as possible to Dr. William B. Peck, Managing Director, Freeport, Illinois. Preference in the assignment of hotel and steamship accommodations will follow the order in which the applications are received.

AMERICAN DERMATOLOGICAL ASSOCIATION

The next annual meeting of the American Dermatological Association will be held in Minneapolis, June 5, 6 and 7, 1924, with headquarters at the New Lafayette club, where all papers will be given. A skin clinic will be given at the University Hospital in connection with the regular meetings.

Arrangements for the meeting are being made by the local members of the Association, Dr. John Butler, Dr. S. E. Sweitzer, Dr. Charles Freeman and Dr. H. G. Irvine, who, as a member of the Council, is acting as chairman.

AMERICAN SOCIETY OF CLINICAL SURGERY

Announcement has been received of the semi-annual meeting of the American Society of Clinical Surgery, which is to be held in Rochester, Minnesota, June 6 and 7, 1924.

RED RIVER VALLEY MEDICAL SOCIETY

At the annual meeting of the Red River Valley Medical Society which was held in Crookston in January, the following officers were elected for the coming year: President, Dr. W. H. Hollands, Fisher; vice president, Dr. Arthur Kahala, Crookston; secretary-treasurer, Dr. M. O. Oppegaard, Crookston.

STATE MEDICAL MEETING

The annual meeting of the State Medical Association will take place October 8-10, 1924, at St. Cloud. The program committee consisting of the chairman and secretary of the Surgical Section, Dr. A. C. Strachauer, Minneapolis, and Dr. V. C. Hunt, Rochester, the chairman and secretary of the Medical Section, Dr. E. L. Tuohy, Duluth, and Dr. C. N. Hensel, St. Paul, and the secretary of the Association, had its first meeting February 13. The various problems in the arrangement of a comprehensive program were discussed. It was decided to arrange a program similar to previous state medical programs, affording an opportunity for members of the Association to present subjects in which they are particularly interested and which will be of interest to the members. Members are invited to send in to the secretary of the Association, 402 Guardian Life Bldg., St. Paul, the titles of subjects they desire to present. It will of course be incumbent on the committee to pick and choose in order to make up a well balanced program. Titles must be in the hands of the secretary by *April 15*. Prompt notification of acceptance or rejection will be made about May 15.

THE MEDICAL FORUM

The Medical Forum of St. Paul held its regular monthly meeting Wednesday evening, March 5, 1924. After a dinner at the Saint Paul Hotel the following program was given:

1. Case Report. Pyo-nephrosis, treated by ureteral drainage. This interesting case was fully presented by Dr. E. H. Norris, who emphasized the possibilities and the success of this method of drainage, where other surgical intervention might be contraindicated. General discussion of the case was opened by Dr. F. E. B. Foley.

2. Practical Electrocardiography, with lantern slide demonstration. This subject was presented by Dr. H. E. Richardson, who emphasized the diagnostic, prognostic, and therapeutic aids given by this instrument of precision, the electrocardiograph, especially in cardiac irregularities and in the myocardial degenerative diseases of middle life. He urged a more general use by the medical profession of the information given by this instrument in the interest of more accuracy in the diagnosis and treatment of diseases of the cardio-vascular system. General discussion of the subject was opened by Dr. E. T. Herrmann.

The next meeting of the Medical Forum will be held at the Saint Paul Hotel, April 2, 1924.

W. R. SHANNON, President.

L. S. YLVISAKER, Secretary.

OF GENERAL INTEREST

Dr. J. V. Johnson of Duluth has moved to California.

Dr. L. Q. Greeley of Duluth has been doing some postgraduate work at Chicago.

Dr. F. D. Brandenburg, formerly of New Richland, is now located at Crystal Bay.

Dr. and Mrs. D. E. Seashore of Duluth spent the month of February at Miami, Florida.

Dr. T. N. Kittelson of Fergus Falls recently returned from a trip to Mobile, Alabama.

Dr. S. H. Boyer was recently elected president of the Professional Men's Club of Duluth.

Dr. and Mrs. L. D. Huffman, Rochester, are the parents of a daughter born February 11, 1924.

Dr. and Mrs. Tolbert Watson of Albany have returned from a trip through the western states.

Dr. and Mrs. C. E. Lum of Duluth have returned from a month's visit in Los Angeles, California.

Dr. J. W. Ekblad of Duluth spent the month of February at the home of his parents in Kansas.

Dr. M. B. Bonta, Rochester, recently returned from a three weeks' clinical trip to New York and Boston.

Dr. H. B. Grimes of Madelia was re-elected for his third successive term as mayor of Madelia at the 1924 election.

At a recent meeting of the Northwest Pediatric Society, Dr. H. G. Irvine, Minneapolis, gave a paper on "Infantile Eczema."

Dr. W. C. Portmann of Jackson, who is now on the Pacific coast, will return to his practice at Jackson about the middle of April.

Dr. E. J. Pengelly of the Cuyuna Range Hospital, Crosby, is now in Chicago, where he is doing postgraduate work in medicine and surgery.

Dr. W. J. McCarthy of Madelia resigned as president of the local school board at a recent meeting, following twenty years of service on the board.

Plans are being made for the construction of a twenty-five-bed hospital at Morris. The building will be of brick construction and will be fireproof throughout.

Dr. E. W. Fahey, Duluth, has been appointed to succeed the late Dr. E. W. Buckley of St. Paul as supreme physician for all lodges of the Knights of Columbus.

Dr. L. E. Claydon of Red Wing has returned from a two months' visit at his former home in England. While there he visited the principal clinics of England and Scotland.

The contract for the interior finishing of St. Luke's Hospital of Duluth was let March 21st. It is planned to have the building ready for occupancy by the first of next year.

Drs. G. A. Paulson, P. F. Eckman, and M. G. Gillespie, all of whom recently completed their internship at St.

Mary's Hospital of Duluth, have located in that city permanently.

Dr. H. G. Reineke of New Ulm is now located in Villard for the practice of his profession. Dr. Reineke was formerly associated with his father, Dr. George F. Reineke, at New Ulm.

Dr. William H. Barr of Wells has been appointed a member of the State Board of Medical Examiners to succeed Dr. A. F. Schmitt, formerly of Mankato, now of Minneapolis.

Dr. D. W. McDougald, who recently completed a course in postgraduate study in New York, is now located at 400 East Hennepin Ave., Minneapolis, for the practice of his specialty in eye, ear, nose and throat work.

Three new members have been added to the staff of Dr. C. T. Granger of Rochester: Dr. R. W. Allen, specialist in obstetrics; Dr. J. N. Guthrie, ear, nose and throat specialist, and Dr. Clara G. Cook, who is a specialist in the diseases of children.

The Goodhue County Medical Society has endorsed the work of the County Health Association and the Red Wing Visiting Nurses Association in establishing children's clinics. Dr. W. D. Beadie of Cannon Falls will be in charge and one or more local physicians will be associated with him in each city where the clinics are held. The first clinic was held at Red Wing on March 11th and was well attended.

Dr. J. W. Andrews of Mankato has returned from a trip to Florida, where he spent the winter months. Dr. Andrews has sold his interests in the Mankato Clinic, but will retain office room in the Clinic building, where he will be able to meet old friends and patients. Although retiring from active clinical work, Dr. Andrews will continue a private practice. He is numbered among the oldest active practicing physicians in Minnesota.

Dr. E. A. Meyerding resigned as director of hygiene in the St. Paul schools, March 17, to take up his new duties as executive secretary of the Minnesota Public Health Association and the management of the *Northwestern Health Journal*. Dr. Meyerding inaugurated health work in the St. Paul public schools in 1909 with a staff of two, himself and one nurse. The department now numbers eighty-five employees. Dr. Meyerding succeeds Dr. W. F. Wilde as executive secretary of the Minnesota Public Health Association, of which Dr. H. Longstreet Taylor, St. Paul, is president.

New Prague is to have a new Community Hospital through the generosity of Mr. and Mrs. W. L. Harvey, formerly residents of the town. Recently they presented the locality with their handsome residence for conversion into a hospital. The building was thoroughly inspected by a committee, assisted by Dr. L. B. Baldwin, superintendent of the University Hospital, and it was determined that with slight changes, the building will be suitable for hospital purposes. An association has been formed and a sufficient fund is being raised to start the project. The hospital will be run on a cost basis, and it is hoped will be in operation this spring.

Mr. and Mrs. C. E. Friedrich and Miss Helen Friedrich of Red Wing, Minn., have given \$35,000.00 to the Red Wing Hospital Association to be used for the erection of an addition to the Red Wing Hospital. Mr. and Mrs. Friedrich give \$20,000.00 as a memorial to their son, Edward H. Friedrich, and Miss Friedrich gives \$15,000.00 as a memorial to her mother and to her brother, John H. Friedrich. A large frame building, which was built by Gen. Jennison and later was the original hospital, will be removed to an adjoining lot and remodeled into a nurses' home. The sum necessary for this purpose, about \$5,000.00, will be raised by subscription.

OBITUARY

DR. THEODORE C. LUND

Following an illness of but a week's duration, Dr. Theodore C. Lund of Hutchinson died at his home, Monday, February 25, 1924. Death was due to pneumonia. Dr. Theodore Christian Lund, son of Rev. and Mrs. J. Th. Lund, was born in Minneapolis on December 6, 1891, being 33 years of age at his death. With his parents he lived for a time at Blair, Nebraska, and at Salt Lake City, where he first took up his medical studies. He was graduated from the University of Minnesota medical college in the year 1917. At the outbreak of war he was stationed at a hospital in New York City. He enlisted in the service and was placed on the medical reserve list, but was not called for active duty. He returned to Hutchinson in 1919 and since that time had practiced his chosen profession. In this short time he built up an extensive practice and won a host of friends by his ever congenial and pleasant disposition.

On August 10, 1916, at Brush, Colo., Dr. Lund was united in marriage to Miss Christina Danielson of Brush. To this union were born two children, Jane, age 5, and Ruth, age 2, who together with their mother are left to mourn the loss of a kind husband and devoted father.

Dr. Lund also leaves to mourn his untimely death, his father and mother, Rev. and Mrs. J. Th. Lund, Minneapolis; three sisters, Mrs. Marcus Beck of Blair, Neb.; Mrs. Chris Betker of Hutchinson, and Miss Beulah, besides numerous relatives and friends.

DR. JACOB L. HOFFMAN

Dr. Jacob L. Hoffman, a practicing physician at Henning for the past twelve years, died in Minneapolis at the age of 59 years, February 6, 1924.

Dr. Hoffman was born in the province of Trondhjem, Norway, June 2, 1865. His father was a physician and he sent Jacob at an early age to the Christiania medical college. He graduated with high honors, there being but one other student in his class that ranked higher. Later he went to Berlin and studied for one year. He came to America about 25 years ago, first practicing his profession in Eau Claire, Wis. He went to Elbow Lake, where he practiced several years before coming to Henning 12 years ago. He is survived by a wife and three children; also by his father, mother, four sisters and two brothers, who reside in Norway.

DR. JOHN S. SEELEY

Dr. John S. Seeley, graduate of the University of Michigan, 1876, died March 2, at Faribault, at the age of 71. His first work in Minnesota was at Cordova, Le Sueur County. Since then, for 39 years, he practiced at Faribault.

DR. J. A. McAULIFFE

Dr. J. A. McAuliffe of Duluth died March 23, 1924, at St. Mary's Hospital, where he had been a patient since suffering a stroke of apoplexy nearly two years ago.

NEW AND NON-OFFICIAL REMEDIES

The following articles have been accepted by the Council on Pharmacy and Chemistry:

ABBOTT LABORATORIES:

Butesin Picrate

Butesin Picrate Ointment

PARKE, DAVIS AND CO.

Dibromin

E. L. PATCH CO.:

Patch's Flavored Cod Liver Oil

VITALAIT LABORATORY OF CALIFORNIA:

Vitalait Culture Bacillus Acidophilus

WILSON LABORATORIES:

Epinephrin-Wilson

Epinephrin Powder-Wilson.

Epinephrin Solution, 1:1,000-Wilson

Corpus Luteum-Lederle.—The fresh substance from the corpora lutea of the hog or cow, dried and powdered. For a discussion of the actions and uses of ovary preparations, see New and Non-official Remedies, 1923, p. 210. Corpus luteum-Lederle is supplied in the form of 2-grain tablets only. Lederle Antitoxin Laboratories, New York.

Corpus Luteum Extract-Lederle.—A sterile solution of those constituents of the corpus luteum which are soluble in water containing sodium chloride 0.85 per cent, sodium citrate 1 per cent and chlorbutanol 0.5 per cent. Each c.c. contains 0.02 gm. of soluble matter in addition to sodium chloride, sodium citrate and chlorbutanol. For a discussion of the actions and uses of ovary preparations, see New and Non-official Remedies, 1923, p. 210. The preparation is marketed in 1 c.c. ampules and in 5 c.c. vials. Lederle Antitoxin Laboratories, New York.

Ovarian Residue-Lederle.—The residue from the fresh ovaries of the hog or cow after the ablation of the corpus luteum, dried and powdered. For a discussion of the actions and uses of ovary preparations, see New and Non-official Remedies, 1923, p. 210. Ovarian residue-Lederle is supplied in the form of 3-grain tablets only. Lederle Antitoxin Laboratories, New York.

Silver Nitrate Solution 1 Per Cent-Lederle.—An aqueous 1 per cent solution of silver nitrate contained in ampules composed of beeswax. The preparation is intended for the prophylaxis of ophthalmia neonatorum. For use, a pin hole is made in the ampule and, after suitable preliminary cleansing of the eye, two drops are placed in each eye of the newborn. Lederle Antitoxin Laboratories, New York.

Whole Ovary-Lederle.—Whole ovarian glands of the hog or cow, freed from extraneous matter and dried at or below 38 C. For a discussion of the actions and uses of ovary preparations, see New and Non-official Remedies, 1923, p. 210. Whole ovary-Lederle is supplied in the form of 5-grain tablets only. Lederle Antitoxin Laboratories, New York. (Jour. A. M. A., Feb. 2, 1924, p. 391.)

Flumerin-H. W. and D.—Disodium-2-hydroxymercurifluorescein. The disodium salt of 2-hydroxymercurifluorescein. Flumerin-H. W. and D., when injected intravenously, is tolerated by rabbits in doses containing from eight to twenty times the amount of mercury present in the therapeutic dose of other mercurial drugs commonly used. When injected into rabbits with syphilitic lesions, the drug brings about resolution of the lesions without apparent injury to the kidney. When injected intravenously into man in doses of 3 mg. per kg., flumerin has caused the disappearance of spirochetes from primary and secondary syphilitic lesions. Flumerin has brought about resolution of the lesions and in about one-half the cases changed a positive blood Wassermann reaction to negative. In tertiary syphilitic lesions resolution of the lesions with a disappearance of a positive Wassermann was brought about in a majority of cases treated. The dose of flumerin-H. W. and D. is from 0.002 to 0.005 gm. per kg. of body weight injected intravenously in 2 per cent aqueous solution. The drug is marketed in tubes containing respectively 0.15 gm., 0.20 gm., 0.25 gm. and 0.30 gm. Hynson, Westcott and Dunning, Baltimore. (Jour. A. M. A., Feb. 9, 1924, p. 469.)

Epinephrin-Wilson.—A brand of epinephrin-N. N. R. Made from the suprarenal gland. For a discussion of the actions, uses and dosage of epinephrin, see New and Non-official Remedies, 1923, p. 112. Epinephrin-Wilson is marketed in the form of epinephrin powder-Wilson (vials containing epinephrin-Wilson, 1 grain) and epinephrin solution, 1:1,000-Wilson (containing epinephrin sulphite equivalent to 1 part epinephrin-Wilson in 1,000 parts of physiological solution of sodium chloride). Wilson Laboratories, Chicago. (Jour. A. M. A., Feb. 23, 1924, p. 531.)

PROPAGANDA FOR REFORM

Immunization Against Typhoid.—Ordinarily typhoid vaccine is administered at intervals of seven days. It is said that if the interval is less than seven days, the immunity may be less than after longer intervals. It is asserted also that the maximum response follows when the intervals between the injections are lengthened to eighteen or twenty days. No definite statement can be made as to what the optimal intervals really are. Immunity after anti-typhoid inoculation is not absolute. Army medical officers express the opinion that immunity from inoculation begins to decline in from two to two and one-half years; but even after four and five years, the typhoid rate of inoculated troops has been estimated at about one-fourth that of uninoculated troops. (Jour. A. M. A., Feb. 2, 1924, p. 411.)

The Absorption of Epinephrin.—Although epinephrin is absorbed from the mucous membranes of the nose, throat, mouth, urethra, vagina and rectum, the effectiveness of such modes of introduction is too uncertain to make them popular. The drug is not absorbed from the gastrointestinal

canal to induce any appreciable effect. Intravenous administration must be used with extreme caution and the manifestations secured are likely to be rather evanescent. The response to intramuscular injection is considerable. There is a widespread belief that the subcutaneous administration of epinephrin causes little effect and that the action is decidedly uncertain. However, the relief which is secured from the hypodermic injection of epinephrin in asthmatic patients is evidence that absorption by this route is rapid and satisfactory. It probably proceeds by lymphatic rather than by blood vascular channels. (Jour. A. M. A., Feb. 9, 1924, p. 473.)

The Insulin Reserve.—It is highly probable, according to R. N. Wilder, that patients with the acute type of diabetes will in a few years lose all native tolerance for glucose, and become completely dependent on insulin. In such cases, 37 units (old standard) of insulin may be required, and in some cases as much as 56 units a day. A partially diabetic patient may suddenly be converted into a totally diabetic patient by infection and, therefore, a month's supply of insulin should be kept on hand. Reginald Fitz and William P. Murphy state that there are two classes of diabetic patients: those to whom insulin is a luxury and those to whom it is a necessity. They hold that the wise physician will conserve the use of insulin to the cases of such diabetic patients as can dispense with it or use only small amounts and will hold it in reserve as an indispensable product, for the patients who require large amounts in order to secure definite results. (Jour. A. M. A., Feb. 9, 1924, p. 473.)

Treatment of Pernicious Anemia.—Arsenic and blood transfusion are the two established forms of therapy in the treatment of pernicious anemia, though neither is curative. Arsphenamin in doses of 0.03 to 0.06 gm. intramuscularly at intervals of days or weeks has been found useful in some cases, though it has failed in others. (Jour. A. M. A., Feb. 9, 1924, p. 491.)

Ichthyol and Ichthalbin Omitted from N. N. R.—The Council on Pharmacy and Chemistry publishes a report announcing the omission of Ichthyol and Ichthalbin from New and Non-official Remedies and a report on the therapeutic value of Ichthyol on which the deletion of Ichthyol and Ichthalbin is based. Ichthyol was introduced into dermatology about forty years ago, and it came into wide use during its skillful exploitation. It has been difficult to obtain acceptable evidence concerning the therapeutic value of Ichthyol. The opinion in regard to its value has been divided, with good observers on both sides of the question. After some years of consideration and doubt, the Council has come reluctantly but decisively to the conclusion that there is no satisfactory evidence that Ichthyol has any therapeutic value other than that of a mild antiseptic and that of being soothing to inflamed mucous membranes. Merck and Co., who market the product in the United States, declined to limit their claims so as to harmonize them with the views of the Council, and, therefore, the Council has omitted Ichthyol from New and Non-official Remedies. The Council also omitted Ichthalbin, marketed by E. Bilhuber, Inc., New York. Ichthalbin is described as a compound of ichthyolsulphonic acid and albumin. Its actions are stated to be essentially the same as those of Ichthyol. Therefore, E. Bilhuber, Inc., was informed that,

unless the therapeutic claims made for Ichthalbin conformed to the claims permissible for Ichthyol, Ichthalbin would be omitted from New and Non-official Remedies. Circulars in use during 1922 contained recommendations for the internal use as an intestinal antiseptic and in skin diseases. Since these claims were incompatible with the evidence obtained by the Council, Ichthalbin was omitted. (Jour. A. M. A., Feb. 16, 1924, p. 565.)

Carbon Tetrachlorid for Hookworm.—Carbon tetrachlorid is at present obtaining such an amount of favorable notice that, unless subsequent experience demonstrates as yet unknown dangers, it may be considered a suitable method for the treatment for hookworm. The drug is palatable, requires no preparation of the patient and is relatively non-toxic. The only fatal results so far recorded were associated with the use of an impure product. The commercial product is unfit for use. Hence, the New and Non-official Remedies quality should be insisted on by prescribing carbon tetrachloride Medicinal-N. N. R. The dosage generally recommended is 0.2 c.c. (3 minims) for each year of life; with an adult, a dose not exceeding 3 c.c. In prescribing, one may order twice the amount indicated for a single dose, and the patient may be instructed to repeat the dose at an interval of fourteen days. It is simply administered from a tablespoon which has been half filled with sweetened water. It is usually best to administer magnesium sulphate two hours after the drug is given. (Jour. A. M. A., Feb. 16, 1924, p. 569.)

PROCEEDINGS OF THE MINNESOTA ACADEMY OF MEDICINE

MEETING OF FEBRUARY 13, 1924

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, February 13, 1924, at 8 o'clock. The meeting was called to order by the President, Dr. Hamilton. There were thirty-eight members and five visitors present.

The minutes of the January meeting were read and approved.

The following members reported cases:

1. DR. E. L. TUOHY (Duluth) gave a résumé of cases and records, and a method of showing typewritten data on lantern slides.

Lantern slides were shown with very abbreviated summary of case records. This typed material was fastened to the ordinary lantern slide, according to a method which makes unnecessary any photography whatever. Lantern slides can be made in a matter of a very few minutes by typing directly upon what is known as "Radio-Mat" slides.*

A case was shown with lantern slide of the roentgen picture of the lungs, which prior to autopsy was taken to be miliary tuberculosis. This diagnosis was substantiated by the gross examination of the lungs themselves. However,

the microscopic examination of the tissues revealed miliary carcinomatous metastases, and the original source was found to be annular scirrhous carcinoma near the pylorus.

A record was shown of a forty-five-year-old woman, with moderately advanced pulmonary tuberculosis. Her gastrointestinal symptoms were attributed to either the toxemia of the advancing tuberculosis, or late invasion of the gastrointestinal tract, resultant from the terminal depression of her vitality and immunity. On autopsy a few small ulcers were found in the intestine, and a very few tubercles over the surface of the peritoneum. However, a definite large, non-tuberculous gastric ulcer was found. (Specimen was shown.)

The record of a man, aged 50, was shown, who had fully-proven chronic endocarditis with mitral stenosis and auricular fibrillation. A period of restored health was interrupted by much gastric irritability. It might have been assumed that this was entirely secondary either to digitalis medication or to the common visceral congestion incident to the heart state. On the contrary, careful roentgen investigation and analysis of his gastric distress and food relief, established with certainty the diagnosis of duodenal ulcer. The customary frequent feedings and alkalies have very promptly given him relief.

A case record was similarly shown of a man, aged 33, with an early history of throat infection, otitis media and running ears. Recently he developed dyspeptic signs, with characteristic food relief, two or three hour pain after eating, etc. This state of affairs yielded in a short time to a situation in which he did not have food relief nearly so constantly, and his distress followed soon after eating, with a burning sensation in the epigastrium communicated up into the chest. Careful roentgen studies showed up a definite defect in the duodenum but in addition also a penetrating ulcer in the lesser curvature. The latter was evidently of more recent origin, or at least activity, than the former. Realizing the great importance of focal infection and the situation obtaining with his running ears, this was the quandary: one of his ears is good; the other is bad from the standpoint of hearing; what advantage would there be by taking a chance of operating upon his bad ear, to limit focal infection, without attacking the other? Is it not better for him to take a chance even with his ulcer, an ordinary treatment, than to endanger the good hearing he has in one ear by radical operation?

Three cases were shown in brief in which at autopsy primary carcinomata of the bronchi were proven up. In all of these cases metastases had occurred to the spinal column (illustrating the accepted frequency of this type of bony invasion on the part of bronchial carcinoma).

One of these cases presented itself with an outspoken swelling over one parietal bone, strongly suggesting lues. A biopsy readily showed it to be a malignant metastasis.

In only one of these three cases was there particular cough or manifest chest symptoms. It can be said at least that without very careful and accurate post-mortems the origin of these malignancies would have been overlooked, and thereby the probable frequency of primary carcinoma of the bronchial tubes underestimated.

*These sheets can be secured from any of the dealers in moving picture equipment and materials.

One of these cases presented the curious picture of definite kidney tumor, which with easily recognizable metastases into the spine made the probable diagnosis of the fairly common condition of hypernephroma most likely. The autopsy in this case showed bilateral hydronephrosis incident to calculi, shadows of which did not appear in the original spine pictures taken with the intention, because of obvious spinal compression, to show vertebral column detail.

2. DR. A. E. BENJAMIN reported a case of obstructive jaundice.

Mrs. S., age 48, female, weight 210 pounds, farmer's wife.

Family History: Father died of tuberculosis. Mother 82, in poor health. Four brothers well, one died in infancy. Three sisters well, one died aged 42 of gall stones.

Personal History: Has had children's diseases. "Stomach trouble for years." Attacks of acute indigestion from special foods. Attacks would last twenty minutes. Would become distended with gas, and had vomiting spells. Considerable belching of gas. Bowels habitually constipated. Saline cathartics would relieve her of some of the stomach symptoms. Has always had kidney trouble.

Complaint: Taken ill about the middle of November. Very nervous. Pain in lower part of abdomen. No backache except low down, across the hips. No pain over gall bladder. Pain would extend to left, under ribs. Jaundice began about Thanksgiving time,* but not marked until about three weeks ago. Itching began at night when nervous. Would scratch and cause bleeding. Some subcutaneous hemorrhage about January 20th. Spots enlarged and spread. Few vomiting spells.

Chief Symptoms: Jaundice and hemorrhagic painful swelling, anorexia, delirium.

Examination: Skin markedly jaundiced. Heart, lungs, nose, throat, and pelvis negative. Subcutaneous hemorrhagic areas throughout skin, especially on abdomen and limbs. Considerable swelling of left leg, resembling thrombosis.

Laboratory report: Bleeding and clotting time—45 minutes. Hgb. 50% (Dare). Red cells 3,180,000.

Diagnosis: Pre- and post-operative, and pathological after autopsy—"obstructive jaundice."

Treatment: January 18th, 1924. Local anesthesia, vein at elbow exposed. Five c.c. 10 per cent sol. of calcium chloride injected slowly. January 19th, 1924. Local anesthesia, old incision at elbow opened. No vein available. Vein in foot was used. Five c.c. calcium chloride injected. January 19th, 1924. In evening, blood transfusion, given 500 c.c. Patient died late at night, January 19th, 1924.

Autopsy report (Dr. J. S. McCartney, Jr., pathologist): Autopsy limited to examination through abdominal incision.

The body is that of a very obese white woman, 167 cm. in length and weighing at least 210 lbs. Rigor mortis is present. There is hypostasis posteriorly; no edema or cyanosis. Scattered over the trunk and extremities are numerous small blood encrusted areas. These in the beginning are said to have been petechiæ but now are covered by crusts. Scattered over the surface of the body are nu-

merous bluish black irregular areas which are not due to hypostasis and clinically were large hemorrhages. The body shows marked jaundice (grade 3). The pupils are equal and regular.

Abdominal incision made. The subcutaneous fat over the abdomen is 5 cm. in thickness. In the fat in the incision an area of hemorrhage is found in the epigastric region. The peritoneal cavity contains no abnormal fluid. Scattered over the intestines are numerous subserosal hemorrhages, some of which reach 1 cm. in diameter; the majority are less than 5 mm. There is marked retroperitoneal hemorrhage, particularly posterior to the cecum and sigmoid. That about the cecum extends beneath the peritoneum onto the anterior abdominal wall. There are a few fibrous bands between the gallbladder and the duodenum.

The pleural cavities and lungs palpated through the diaphragm; no lesion made out. The heart on palpation is normal in size; it is not removed.

The spleen is about normal in size. It is flabby. External surface is slightly wrinkled. On section it is light red in color and the markings are rather indistinct.

The liver is of about normal size. The external surface is smooth. On section the organ is markedly bile stained, the centers of the lobules being prominent. The gallbladder contains several dozen faceted calculi, yellowish white in color and averaging about 6 mm. in diameter. The cystic duct is very markedly dilated, measuring about 8 mm. in diameter. Calculi are found within the cystic duct. The common bile duct is a little larger than the cystic duct and in it calculi are also found; one about 3 mm. in diameter is found just inside the ampulla. The common hepatic duct is about the size of the dilated cystic duct. Calculi are also found within it and in the right and left hepatic ducts up into the substance of the liver. No calculi are found farther than a point 3 cm. above the beginning of the common hepatic duct. The opening through the ampulla is of about normal size.

The stomach contains some cloudy mucoid material. No gross lesions are found in the mucous membrane. The pancreas is about normal in size and shows some fat replacement of the parenchyma. On following out the pancreatic duct it is found to open into the intestine through the ampulla separate from the common bile duct.

The right kidney weighs 140 grams, the left 150 grams. The capsules strip readily, leaving smooth surfaces. On section the organs show marked bile staining and are slightly swollen and cloudy. A few petechiæ are found in the pelvis.

The uterus, tubes and ovaries are apparently normal. The abdominal aorta shows a slight senile change. No further examination of this body is made.

Diagnoses:

1. Calculus obstruction of the common bile duct.
2. Dilation of common, hepatic and cystic ducts.
3. Moderately distended gallbladder.
4. Calculi in gallbladder, cystic, common bile and hepatic ducts.
5. Nephrosis of jaundice.
6. Marked jaundice.
7. Cutaneous hemorrhage.
8. Retroperitoneal hemorrhage.

3. DR. J. F. HAMMOND reported the following case:

This case was admitted to the City Hospital on February 3, 1924. A girl, 17 years old, missed a period the first part of January and thought she was pregnant. She inserted a

catheter with a wire stylet. The following day she began to bleed and had a good deal of pain. Three days later the pain was more marked in the lower abdomen and a physician was called who took care of her from that time until she was admitted to the hospital on Feb. 3, 1924.

On admission it was difficult to get much history. Apparently she had had a stormy time. She did not give any history of chills but had a lot of pain and a good deal of bleeding. She was admitted to the hospital in the early morning of the 3rd. When I saw her on this date she was very much distended, the abdomen being quite prominent. Temperature 104. No pain or tenderness, but marked distention and very rigid. She had a cough; I examined the chest, and the signs were a little irregular. I thought I found some dullness in the back on the right side. The breath sounds were markedly diminished and I thought she probably had some fluid. The liver dullness was completely obliterated. I wanted to find out about the chest condition and thought the easiest way was to take a picture of it. (X-ray shown.) Both lungs were compressed to about the level of the third costal cartilage; the peritoneal cavity was distended with air. The patient seemed to be in extremis. Dr. Drake, Dr. Hall and Dr. Daugherty saw her with me. Nothing much could be made out in the

abdomen, but we felt we might drain her from below and improve her temporarily. We gave her a little ethylene and made a vaginal section. At least a gallon of pus and a large amount of air were evacuated. Cultures did not show that there was any bacillus aerogenes infection.

Although the abdominal distention went down considerably, four days later she was still having a good deal of labored breathing, the liver dullness was still obliterated, and I felt it might be well to drain from above. Under ethylene I made an opening just above the pubes. It was very interesting to see the way the intestines were walled off. Between the omentum and the abdominal wall there was a space one could insert the hand without obstruction from the pelvic cavity to the top of the liver. Care was taken not to open the omentum, thus exposing the lesser peritoneal cavity.

Following this opening the liver dullness returned, and the abdomen was quite flat. The patient's breathing was improved. The day after the vaginal section an enema which was given promptly returned through the vaginal drain indicating a perforation low down in the intestinal tract.

This patient is still having a very bad time; she is very septic, and pulse is weak. She is somewhat cyanosed at times. The outcome is very doubtful.

NOTE: Since reporting this case on February 13th, 1924, the patient died on February 15th. I did not see the autopsy as I was out of town. The report states there was an abscess with feces between the liver and the diaphragm, also about the spleen. The only perforation mentioned was in the cecum. This would not coincide with the fact that an enema given returned at once through the vaginal drain.

DISCUSSION

DR. A. SCHWYZER: I think this is a very unusual case. The picture shows the enormous upward bulging of the diaphragm. This reminds me of a case of splenic anemia where we removed the spleen after it had been reduced by radium, and when we looked up into that dome of the diaphragm it had receded in an extreme manner on the left side. Every heart-beat made a wave-like undulation on this paralyzed and highly receded diaphragm. X-ray showed that for about two weeks it worked very little. It might be that we had to figure with a paralysis from an over-distention of the diaphragm. The case of Dr. Hammond illustrates how valuable the omentum is. Here is shown one of the most important functions of the omentum.

DR. M. S. HENDERSON (Rochester) read his thesis, entitled "Osteochondromatosis of the Hip Joint." (See page 261.)

DISCUSSION

DR. GEIST: Dr. Henderson has presented a topic of real scarcity. I have not seen disease of this type in the hip joint. Jones' work, to which Dr. Henderson refers, was done in Rochester and is a model of modern clinical research. The first case of this kind I ever ran into was

about 12 years ago, and involved the ankle; all my other five or six cases have been in the elbows and knees. The ankle case was a heavy man, weighing over 300 pounds. He had symptoms rather similar to locking of the knee joint; he had the sensation of being thrown and consequent effusion. The x-ray showed three or four bodies in the joint. On opening the ankle the bodies were easily recognized. There were six or seven bodies entirely loose within the joint. In addition to this, there existed about fifteen or twenty small osteo-cartilaginous bodies which were still attached by means of pedicles to the synovial membrane. In fact, some of the pediculated bodies looked like enlargements of normal synovial villi. Some of the pedicles were fairly strong and others were so frail that they were about ready to give way.

All of my cases were in adults and it is very interesting to find Dr. Henderson's case existing in an adolescent. I think Dr. Henderson is to be thanked for presenting this very interesting topic. I should like to ask Dr. Henderson what method of approach he used in opening the hip joint.

DR. A. SCHWYZER: About a year ago I had a case which does, however, not quite belong to this group. Laying all the muscles back from the outer iliac fossa and thus freely exposing the hip joint, we could open it, dislocate the femur very well and see all the parts. At the lower border of the capsule near the acetabulum there were bodies, some of them attached only by a thread, some rather large and hard, and some of them boggy. I was quite impressed by the ease with which we could see all the parts of the joint after cutting the capsule wide open and dislocating the femur. There were no loose bodies, but they were attached by thin pedicles.

I think the case of Dr. Henderson is an unusually pretty one and the x-ray pictures are very fine.

DR. HENDERSON, in closing: The incision used was the Smith-Peterson incision, which in reality is a combination of the old Larghi incision and the ordinary straight incision. We stripped the muscles down freely from the iliac bone, thus coming down upon the top of the joint. We then made a straight incision through the capsule and proceeded to remove the loose bodies.

Dr. Schwyzer's point is well taken. It might have been better to have made the incision larger and thrown the head of the bone out just as we do in an arthroplasty. Our hindsight is usually better than our foresight, and this might have given a better approach to the posterior part of the capsule, but of this I am not exactly sure. We might have been able then to reach the bodies in the posterior part of the joint.

I might add that we have used the Smith-Peterson incision now for some time in un-united fractures of the hip where we do a bone pegging operation, and it gives better approach than any other incision.

DR. R. E. FARR gave a talk on "Some Simple But Useful Adjuncts in the Practice of Surgery." Numerous lantern slides were shown.

The meeting adjourned.

JOHN E. HYNES,
Secretary.

TRANSACTIONS OF THE MINNEAPOLIS SURGICAL SOCIETY

STATED MEETING HELD DECEMBER 6, 1923, AT THE UNIVERSITY HOSPITAL. THE PRESIDENT, J. M. HAYES,
IN THE CHAIR

DR. S. R. MAXEINER: Case report of gunshot wound in right arm.

I wish to report this case because I believe it is of unusual interest, not so much perhaps from a scientific point of view as from the fact that an extremely difficult accident case treated by me at the Minneapolis General Hospital, with only a fair result, has, through another accident, been converted into what must be considered a much improved end result.

Mr. John W., age 29, male, single. Occupation, police officer.

Family history negative. Personal history negative—no operations.

Present illness: On December 20, 1920, while on duty with a shotgun squad, patient was accidentally shot in the right arm with a charge of buckshot, the end of the gun being practically in contact with his arm. He presented a large wound on the outer side of the arm and an extensive compound fracture of the humerus. The bullets took an upward direction, several coming out through the shoulder. The wound was treated surgically and the arm put up in a Thomas splint, with the arm in extension because of the difficulty of obtaining traction with the arm flexed. Dakin irrigations were used but suppuration was intense and, twenty days later, the wound was more widely opened. The wound drained for five and a half months and the splint was required for four months. Inflammation produced so many adhesions in and about the elbow-joint that it remained extended and could not be flexed. One year later an attempt, under anesthesia, to flex the elbow failed.

On January 28, 1924, the patient sustained his second accident, when he slipped on the ice and fell on the stiff arm. He again reported to the Minneapolis General Hospital, where he was treated by Dr. Watson, resident surgeon, who put the arm up in acute flexion under general anesthesia without difficulty, the elbow-joint being perfectly free. X-ray examination showed only two small chips, fractures of the epicondyles. Since January 4, 1924, the patient has been under my care as a private case and has been receiving both active and passive motion and massage and now has a range of motion of more than 45 degrees, with the arm in a much improved position. I hope not only to keep what we have gained but, by continued physiotherapy, to improve his present condition.

In this case the second injury undoubtedly broke up adhesions which we could not do under anesthesia. The x-ray at present shows what appears to be a hypertrophic arthritis.

DR. STRACHAUER presented the following cases:

Case 1. *Partial Gastrectomy*.—Cancer of the stomach. Patient 65 years of age. Operation performed under perfect local anesthesia due to the extreme enfeeblement, emaciation and chronic bronchitis of the patient.

Case 2. *Resection of Gastric Ulcer and Posterior Gastroenterostomy*.—Patient 11 years of age. A pre-pyloric, chronic, calloused ulcer was resected and a posterior gastroenterostomy performed. The patient had a history of ulcer since the age of 8 years, consisting of periodicity pain, nausea and vomiting, food relief, alkali relief, vomiting relief.

Case 3. *Splenectomy*.—Case of Banti's disease in a woman aged 36, on whom splenectomy was performed. Her hemoglobin of 32 per cent was brought up to 40 per cent by several transfusions. Following splenectomy the blood had spontaneously come up to over 60 per cent.

DR. R. E. FARR presented a paper, "Local Anesthesia of the Abdominal Sympathetic System."

DISCUSSION

DR. A. C. STRACHAUER: First, I want to congratulate Dr. Farr on his thoroughly good paper and lantern illustrations. I think the moving pictures are particularly fine. I can fully endorse the stand he has taken tonight regarding local anesthesia, and am especially gratified to have him call attention to the fact that local anesthesia is real anesthesia. A partial obtunding of pain, as is so frequently obtained, is not anesthesia. The defining of the various forms and types of anesthesia is important. The starting of an operation by the injection of a local anesthesia solution and then having to switch on to either ether or gas and terming the anesthesia "local anesthesia" is incorrect; it should be termed a failure. Likewise, the practice of preceding the injection of local anesthesia solutions by injections of scopolamine, morphine and the like, should not be called local anesthesia, but narco-local anesthesia. I believe that Dr. Farr was an ardent advocate of narco-local anesthesia at one time.

I have no patience with the practice of so-called "local anesthesia" preceded by a "knockout" of some narcotic. I have seen, on a number of occasions, patients brought to the operating room so deeply under the influence of scopolamine and morphine that it was wholly unnecessary to use local anesthesia. They were unable to sit up unassisted and did not know where they were. One of the most distressing situations I know is that of an operation being forced through with the patient under only partial local anesthesia, the patient suffering pain and the operator denying that the patient is suffering. Local anesthesia is real anesthesia. With a properly performed technique, local anesthesia can be obtained in the majority of patients.

For a considerable period of my practice, particularly here in the University Hospital, I did something over 80 per cent of my work under local anesthesia, mostly of the blocking type, which I preferred to infiltration, including surgery of the brain, spinal cord, thorax, abdomen, and extremities. At present I prefer general anesthesia as a routine, employing local anesthesia only on special indication, as I feel that with the majority of patients it is better

for psychic reasons that they be not present at their own operations. The cancer of the stomach specimen which I showed this evening was removed under local anesthesia, due to the patient's enfeeblement, advanced age and chronic bronchitis. The choice of the anesthetic may be largely a matter of individuality, and I believe I am becoming more tolerant in this matter of individuality as affecting various surgical practices and procedures. My point is perhaps well illustrated by one of the Magnus Johnson stories. Magnus Johnson was recently consulted in Washington by an "agriculturalist" as to what he considered to be the best fertilizer. His answer was, "Vell, it is all a matter of taste." When visiting in Chicago last spring I found Bevan, Dean Lewis and other co-workers at the Presbyterian Hospital, extremely enthusiastic over ethylene. Dr. Crile and his associates in Cleveland were tremendously enthusiastic over nitrous-oxide analgesia in conjunction with novocain blocking of the field. Ether is the anesthetic of choice at the Mayo Clinic, in Rochester. It seems to me that it is in large degree a matter of taste, as the standard of surgery and the results are of the very highest order in all these centers.

There is no question at all, as I have proved by my work right in this hospital, but that the majority of surgical procedures can be carried out under perfect local anesthesia, but as to whether they should be performed under local anesthesia is another question. I don't want any one to tell me that I should be using local anesthesia to the exclusion of any other anesthetic.

I want to corroborate one more statement of Dr. Farr's and that is concerning the good work in local anesthesia by the younger men, including the internes and Fellows.

In the majority of instances the operator should perform his own local anesthesia. The assistant or interne is usually not familiar with the magnitude of the work to be undertaken and the field of injection is, therefore, frequently, inadequate. In addition to this, it is often necessary to enlarge the extent of the injection as the operation progresses.

As to the subject of splanchnic injection, there is no question as to the choice, the anterior being performed under direct vision and the posterior being a very blind and undependable procedure. In my personal experience it is the exception that the splanchnics require injection. I have performed a number of gastro-enterostomies and resections of the stomach without injection of the splanchnics.

Regarding the great variety of instruments which Dr. Farr has shown this evening, while they are extremely ingenious I know that it is unnecessary to have so much complicated equipment. Local anesthesia "tastes" good to him and all these accessories "taste" good to him, but it is not at all necessary to have so much machinery and paraphernalia.

DR. S. R. MAXEINER: I have always had a deep interest in local anesthesia, due to the fact that, ever since 1909, I have been pretty directly associated with Dr. Farr. In 1909 I was his interne at the General Hospital and in 1910 started with him, where I remained until I went into the Army, and what I have seen and learned of local an-

esthesia has been largely through the experience gained with him. As I traveled over the United States, through the East and elsewhere, I have seen many so-called cases of local anesthesia in which I would agree with Dr. Farr as to the nomenclature. I have also seen cases here in the hospitals where the interne would come to me and tell me that pneumonia followed certain cases of local anesthesia. When asked what the case was he would say, "gall-bladder." Then I would inquire as to whether gas had been used when they got down to the gall-bladder. "Yes." Well, that isn't local anesthesia. I do not say that pneumonia does not follow local anesthesia, but that, in my estimation and in our experience, these patients have had less severe attacks of pneumonia than they would have had following inhalation anesthesia. I recall an instance in one hospital where they had a much higher mortality rate from local anesthesia than from general anesthesia. When comparing their records case for case you would find that the statistics showed that practically all of their "locals" were cases in which general anesthesia was contraindicated. They were cases not suitable for any anesthesia. Dr. Strachauer mentioned the fact that the internes are doing work under local anesthesia. To be sure. During the last two years I have been doing part of the surgery, and during the last six months all of the surgery, at the Government Hospital and my internes have worked with me off and on for a year, assisting in the operating room continuously for six, eight and nine months at a time, without interruption, and I instructed them personally and have watched them develop. One of these boys, who had done probably sixty hernias and I should say forty or fifty appendices with me and under my supervision, now reports that he is out in the country and, without help, doing appendices under local anesthesia. Recently he did one on a kitchen table—an acute case—and had ideal anesthesia. The matter of technic I believe is extremely important in that the tissues cannot be mauled around as they can be under general anesthesia. This, probably, is one of the greatest advantages of local anesthesia. The patient will not have the gas pains, the distention, nausea, vomiting and shock which accompanies the rough handling of the tissues. I believe local anesthesia has taught me more respect for the tissues than any other thing, and the matter of handling the tissues is important. The lifting of the abdominal wall, packing away of the bowels, etc., is extremely important and vision is far more important here than the sense of touch. If, when the abdomen is opened, you have expulsive force with protrusion and intra-abdominal pressure and you can't expose the pelvis, you might as well change to general anesthesia at once. This morning I did a case of double salpingitis in the subacute state, with both tubes and both ovaries plastered down in the pelvis, with 100 per cent anesthesia and perfect negative, intra-abdominal pressure, and when I closed the abdomen at the end of the operation I could overlap the abdominal wall fully one inch because there was absolutely no expulsive pressure. I could not have done this five years ago, because I had not had the amount of experience. It is only when you do a large percentage of your cases under local anesthesia that it is possible to do the difficult ones under local, and negative pressure is

extremely important. It is the indicator of whether you have anesthesia or not.

DR. BRONCHOW (speaking by invitation): I would like to stress one thing Dr. Farr has brought out in his paper, namely, that *prolonged* special training is not required for surgery under local anesthesia. He has a stunt of calling upon his assistant, after being with him for a short time, to make the injection and carry through some abdominal operation with his help. Before coming in to his service as an assistant I had had no special surgical training, as you know. However, I recall one instance shortly after starting with him when he asked me to inject for and remove a subacutely inflamed appendix. The patient was a partially deaf Polish woman, which somewhat handicapped the psycho-anesthetist. However, the procedure was carried out satisfactorily and the anesthesia reported as ideal.

I admit, of course, that I had a good assistant, but most of the assistants here would agree that our chiefs as assistants are better surgeons. Similar experiences could be cited by any of his previous assistants and I am sure that one is not justified in thinking that prolonged special training is necessary provided the fundamentals of local anesthesia as outlined by Dr. Farr this evening are followed. The intra-peritoneal anesthesia, as described, because of its simplicity and practicability will undoubtedly be more widely used and is destined to become the method of choice.

DR. R. C. WEBB: The remarks which have been made concerning the conscious patient during an operation remind me of a recent experience with local anesthesia. A locomotive going at a high rate of speed left the rails and just before it tipped over the engineer went out the window. He received numerous injuries, among which was an inguinal hernia, as a result of the accident. When he had recovered sufficiently from his other injuries I repaired his hernia, using local anesthesia. He appeared to be well satisfied with the anesthesia and stated that I did not hurt him. He stated that the operation was painless, when interviewed a day or so later by a claim agent. When he had recovered and was settling with the claim department for the time lost and for the suffering which he had undergone everything was agreed upon except the hernia. He mentioned the hernia and the operation which he had to undergo and was reminded of his remarks concerning the lack of pain. He said, "Yes, but I think I ought to have something for the strain and agony of lying there on the table during that operation and expecting that he would hurt me."

DR. H. B. SWEETSER: Although I have used local anesthesia in a fair number of cases, I do not think I know enough about it, either to condemn it as many do, or to advocate it so absolutely for all operations as does Dr. Farr. Under certain circumstances and for certain operations I think it ideal, but, as Dr. Strachauer has said, "It is likely to be a matter of taste." In discussing the question of anesthesia, we must take into consideration, first the anesthetic, then the patient and lastly the operator.

If it were a question between a general anesthetic as dangerous as chloroform, for instance, and a local anes-

thetic as innocent as novocain, there could be no discussion as to method. If surgeons were limited to such a choice, then we would all be morally bound, in the best interests of our patients, not only to perfect ourselves in methods of local anesthesia, but to apply them in all cases where possible. But we are *not* so restricted; we *do* have general anesthetics which statistics show are fairly safe if expertly given. It is plainly evident, however, that surgeons are not satisfied with present methods or anesthetics, for constant effort is being made to devise better methods and discover safer anesthetics. This morning I had the pleasure of witnessing for the first time the giving of our latest anesthetic ethylene, here in the University hospital; and many times I have watched Dr. Farr do major operations very ideally with his local methods. At present it may be said that the great majority of surgeons have not concluded that it is necessary to abandon general anesthesia in the interests of their patients.

From the standpoint of the patient it is not all a question of abolition of pain. Many object to being conscious of the operation. But a graver question has to do with the nerve strain endured during a prolonged major operation. I have had patients ask if I were about through even before we had finished the aseptic preparation. If I am able to get perfect local anesthesia, I am willing to go as far as the patient, but if my patient wishes me to shift, I am never so wedded to the idea of success as not to be willing to shift, and I do not feel that I have failed. During thyroidectomy, if the patient gets nervous and asks if we soon will be through, I do not think it fair to keep repeating, "We will be finished in a few minutes," when we know we are not truthful; when this occurs I am glad to pocket my pride and switch to gas-oxygen. In the abdomen, without the expertness of Dr. Farr, I know we can get the much-sought-for negative pressure by blocking and opening the abdominal cavity under novocain, and then continuing with nitrous oxide gas, and no ether. This I think of especial advantage in cases where we are not certain as to what we will find and what we expect to do; it allows us to make a freer and wider investigation and possibly a more complete operation. We have used this combined method for a long time in many cases and have observed the results, and I am sure our mortality rate justifies its continuance. This does not mean that I never complete an abdominal operation under local anesthesia; I do; but that I am not willing to put too great a stress on the patient, as I think, unnecessarily. I was very glad to hear Dr. Farr and Dr. Maxeiner say that when you get expulsive efforts, you might as well quit, and I was very much interested to have them explain why they were so careful in handling retractors because any abnormal pulling or irregular traction might defeat the whole endeavor and compel them to change to general anesthesia. This explains some of my failures, and I intend to reform. Caudal anesthesia we have found very valuable and use it almost exclusively in operations on the perineum and bladder. Some patients are so phlegmatic in temperament that success with local anesthesia is assured, but many are so excitable that most surgeons, except enthusiasts, are not willing to make the trial. Of course, the nervous sys-

tem may be quieted by hypodermic medication, but this is no longer pure local anesthesia, but approaches general anesthesia.

As regards the operator, certain qualifications are essential. First, he must, by study and practice, perfect himself in the best methods. Necessarily, he must learn to handle the tissues with the utmost gentleness. Then he must be honest with himself and not try to deceive himself into believing that he is using local anesthesia while all the time his patient is complaining of pain. In other words, he must be humane. Just a word about the men who say they use local anesthesia. I have been around too many clinics and have seen many operations under so-called local anesthesia, and have shuddered to think that I myself might some day occupy the place of some of these patients. It is really horrifying to watch a patient undergoing a major operation, facing the possibility of death, and suffering pain, and to hear the operator telling him "he is not hurting him," "he is a coward," "he is a baby," "shut up," "lie still, or I'll squirt you in the face," etc. It is not only immoral, it is unchristian and inhuman.

DR. FARR'S closing remarks: I am very much pleased with the discussion and especially that of Dr. Strachauer. It makes me feel that his attitude towards local anesthesia is undergoing considerable change.

This paper was presented with the idea of calling to your attention the facility with which local anesthesia may be used in abdominal surgery as well as to show that there is a widespread belief that its application here is limited. I do not feel that it is necessary to have as elaborate an outfit as I possess for this work. However, equipment and surgical technic are especially important. Neither do I suggest that everyone else should use local anesthesia. I am simply trying to show what *can* be done. I also feel that acquiring the knowledge of how to use local anesthesia is not especially difficult at this time. In the earlier years it was difficult but at present we have an opportunity to see those who are well versed in the application and we may practice the art without harming our patients.

Beginners should not feel that it is a disgrace to be compelled to go to general anesthesia. An operation may be started under local and general may be added at any time that it becomes necessary.

Dr. Sweetser has asked regarding mortality. The question can only be answered provided groups of cases operated upon are alike. Two years after I began doing surgery I did 199 major operations without a death. At the present time I cannot duplicate this performance—I have a wider reputation and the cases coming to me are much more serious. For instance, if 50 per cent of one's operations are for laceration of the perineum his mortality is apt to be low. Someone has said that statistics may be used to prove anything, even the truth. My suggestion is that the method is the most benign yet developed and that it should be simplified as much as possible and that experience with the simpler cases will perfect a surgeon's technic so that he may be able to offer to those who should have local anesthesia its beneficent influence.

ARTIFICIAL PNEUMOTHORAX IN PULMONARY TUBERCULOSIS, A STUDY OF 109 CASES—John T. Farrell, Jr., and Roland F. Fleck (*Amer. Rev. of Tuberculosis*, January, 1924): The indications for pneumothorax given by these writers who summarize the use of the treatment at White Haven Sanatorium, White Haven, Pennsylvania, are as follows: "Hemorrhage or persistent oozing which could not be controlled by simpler methods, failure to respond to routine treatment, and sometimes the idea of the lessening of toxicity by lowering temperature, decreasing expectoration or relieving cough, and in certain earlier cases to test the value of a method which was receiving commendation from other clinicians. Recourse was had to the method only after the patient had been carefully studied by one of the visiting physicians in his private practice, or after residence in the sanatorium. The control of collapse was determined by repeated physical examinations, and later by the combined use of this method and the x-ray, the latter by both the fluoroscope and stereoscopic plates."

Of the 109 cases 45 were improved, 42 unimproved and 22 died in the sanatorium. The percentage of improvement increased with the age of the patient. Patients who had had the disease from one to two years showed less improvement than those who had a history of symptoms extending over less than one year or more than two. The less extensive the involvement the greater was the percentage of improvement. The presence of tubercle bacilli is not a contra-indication to the treatment. Patients improving under preliminary treatment gained the most from the use of pneumothorax. The longer the duration of the pneumothorax treatment, the higher was the percentage of improvement.

ARTHUR T. LAIRD.

THE QUESTION OF THE MOST RELIABLE AUSCULTATORY SIGNS IN THE DIAGNOSIS OF PULMONARY TUBERCULOSIS—Fred H. Heise (*Amer. Rev. of Tuberculosis*, Nov., 1923): Heise examined a group of 1,000 cases. He classified them as follows:

Group	Physical Findings	No. of Cases	Parenchymatous X-ray Changes Per cent	Tubercle bacilli in Sputum Per cent	Clinically Tuberculous Per cent
1.	Broncho-vesicular breathing	248	40	18	59
2.	No abnormal sounds	45	51	22	60
3.	Breathing distant or exaggerated	13	31	..	67
4.	Indefinite râles . . .	36	53	19	72
5.	No râles, upper third of chest . . .	93	67	43	78
6.	Fine râles, upper third of chest . . .	140	78	45	82
7.	Moderately coarse râles, upper third of chest	425	98	47	99

In Dr. Heise's experience râles are the only auscultatory physical signs of any importance in the diagnosis of pulmonary tuberculosis unless breath sound changes are so marked as to approach the bronchial type. A negative physical examination by no means rules out clinical tuberculosis. The presence of broncho-vesicular breathing alone is not a particularly valuable sign of clinical tuberculosis.

ARTHUR T. LAIRD.

TECHNIQUE OF CHEST ROENTGENOGRAPHY—L. T. Black (*Amer. Rev. of Tuberculosis*, December, 1923): The author has endeavored to discuss the impracticability of Bray's technique. Bray's technique is, in brief, taking a posterior-anterior plate with standard and uniform methods, once during suspended costal inspiration, and immediately thereafter, during suspended diaphragmatic inspiration. Posterior exposures were preferred to the usual anterior (face to the plate) exposure, because on abdominal breathing the thorax does not remain in contact with the film owing to the protrusion of the abdomen, thus causing a technical difference which might prove confusing in diagnosis. Certain changes in the densities seen in x-ray plate were attributed to height and depth of the inspiration employed by the patient preparatory to the x-ray exposure. Comparisons were made in the height of the suspended costal inspiration with the height of the diaphragmatic inspiration. On costal inspiration expansion of the lung was manifested by an increase in the circumference of the chest, while on diaphragmatic inspiration, the chest remains immobile, and expansion is effected solely by the descent of the diaphragm. The direction in which the lung expands effects its shape. It is relatively short and thick on costal inspiration but long and narrow on diaphragmatic inspiration. Inasmuch as the hila move in unison with diaphragm, the hilar shadows may be two interspaces lower in diaphragmatic than in costal inspiration; and there may be distinctly appreciable changes in outline density. Annular shadows may be present in one and absent in the other. In certain instances, shadows termed as "hard" and regarded by some observers as denoting fibrosis and inactivity may be converted into shadows which are "soft" and commonly interpreted as evidence of an active lesion.

In a comparative study of roentgenographs, taking the posterior-anterior position during suspended diaphragmatic inspiration and suspended costal inspiration on 25 patients with pulmonary tuberculosis, there were found two cases of far advanced pulmonary tuberculosis in which the roentgenographs taken during suspended diaphragmatic inspiration revealed changes of a definite nature which were not revealed in the roentgenographs taken during suspended costal inspiration, thus corroborating Bray's observations. In a series of 11 cases, roentgenographs in the posterior-anterior position and anterior-posterior position during suspended diaphragmatic and suspended costal inspiration, there was found only one case in which the findings differed during suspended costal inspiration and diaphragmatic inspiration.

In spite of these findings and as a result of a general survey of the situation, considering the diagnosis of these differences and the economic side of the question, it can hardly be recommended that for general diagnostic purposes in pulmonary tuberculosis more than one type of position and inspiration be used. However, the matter of choice for general use rests entirely with the individual case.

J. R. FUCHLOW.

SOME RESULTS OF ARTIFICIAL PNEUMOTHORAX TREATMENT—William H. Morriss (Amer. Rev. of Tuberculosis, January, 1924): Since the opening of Gaylord Farm Sanatorium, Wallingford, Conn., 2,900 patients have been under treatment; 75 cases or 2.6 per cent have received artificial pneumothorax, a very conservative selection, as according to the author 5 per cent has come to be generally accepted as the usual proportion of cases found suitable for such treatment.

Morriss gives indications for pneumothorax treatment as follows:

1. Moderately advanced patients, whose lesion is either entirely confined to one lung, or in whom the lesion of the contra-lateral lung is apparently inactive and does not extend over more area than that portion of the lung above the second chondro-sternal articulation. This group is almost always given a trial on the usual regimen of rest treatment and only on failure to make a decided improvement is pneumothorax instituted. We include also in this group certain minimal cases, who after a fair trial on the rest regimen fail to rid themselves of signs of activity and whose x-ray picture shows a spreading lesion.

2. Moderately advanced or far advanced patients with chronic type of lesion usually associated with cavity formation. Here treatment may be undertaken on the more active lung even in the face of considerable trouble in the other side, in the hope of ameliorating symptoms and getting the patient up and around.

3. Severe or repeated hemoptysis, without a very marked lesion on the other side, provided that the side from which the hemoptysis is occurring can be definitely determined.

4. Very acute unilateral lesion, where x-ray shows a dense mottling confined to one lung. Our feeling here is that collapse should be induced without delay.

The later cases have uniformly been studied with the aid of x-rays.

The selective collapse described by Barlow, that is the tendency of small amounts of gas introduced into the pleural cavity to localize over the portion of the lung showing the greatest evidence of tuberculous activity, was found in 18 out of 38 cases of partial pneumothorax.

The results in the later cases treated were better than in the earlier series.

The late results of the second series (25 cases) show 52 per cent still under treatment, all improved. Of the others, 24 per cent have improved and eight per cent (2) have secured an arrest of the disease. Fourteen per cent only of all the cases in which a pneumothorax was established were treated more than a year.

ARTHUR T. LAIRD.

INTRAPERITONEAL OXYGEN INFLATIONS IN THE TREATMENT OF ASCITIC TUBERCULOUS PERITONITIS—Walter L. Mattick (Amer. Rev. of Tuberculosis, January, 1924). Pneumoperitoneum in the Treatment of Tuberculous Peritonitis—Oscar Monroe Gilbert (Amer. Rev. of Tuberculosis, January, 1924): Oxygen inflation of the peritoneal cavity was first used for diagnosis in 1902 by Kelling. In 1913 Godwin, after four years' experience with oxygen inflations following celiotomy in tuberculous (ascitic) peritonitis, noted the non-recurrence of the condition in patients so treated and was astounded that such a promising procedure was not more generally used. In 1913 Bainbridge described two methods of using oxygen after celiotomy and recommended its use for the following purposes: (1) to lessen shock, (2) to overcome negative pressure on certain types of tuberculous peritonitis, and (3) for effect on pus-producing bacteria and their toxins.

Stewart and Stein gave great impetus to pneumoperitoneum as an aid to x-ray diagnosis in 1919, and it was during the course of their work that Stein noticed the favorable results in cases of tuberculous peritonitis with ascites.

Mattick and Gilbert report three cases in which this method of treatment was used with apparent advantage to the patient, Mattick using oxygen and Gilbert filtered atmospheric air.

Mattick's technique was as follows:

"Operation: On October 27, 1922, under aseptic precautions, according to the above described technique, the patient's abdomen was pierced by the trocar and cannula about 1.5 inches to the left and below the umbilicus. Approximately 40 to 50 c.c. of clear amber fluid was withdrawn. After several attempts to remove more fluid, no more would drain out and oxygen was injected through the same cannula until the patient complained of discomfort from gas distention and liver dullness was obliterated. X-ray pictures were taken within one hour after inflation in both prone and lateral positions."

Gilbert introduced the sterile filtered air by means of a pneumothorax apparatus. All patients had some temporary discomfort.

MAYO CLINIC, ROCHESTER

PAPILLARY TUMORS OF THE RENAL PELVIS—

Albert J. Scholl (Surg., Gyn. and Ob., February, 1924): The majority of tumors of the renal pelvis are of papillary origin. In the early stages they are small, often multiple, flat or thickly pedunculated and confined to the renal pelvis. They grow rapidly and invade the whole kidney pelvis after distending it by masses of the growths. The ureter and bladder often become secondarily involved with transplants.

Hematuria is the most common symptom of this condition. The hemorrhage is usually profuse and may be continuous or intermittent. In differential diagnosis essential hematuria is usually characterized by a long continued mild hematuria with rarely any passage of clots. In cystoscopy a unilateral hematuria is demonstrated and if bladder metastases are present, papillary bladder tumors are seen.

Pyelography often makes the diagnosis certain by the distortion and filling defects. Pain of an aching character may be present over the kidney area and sometimes colicky pains may be present caused by the passage of blood clots. The prognosis is bad. Few remain well and free of metastases.

The treatment consists of nephrectomy with ureterectomy and constant checking up on transplants in the bladder with the cystoscope. If the tumors are too large to fulgurate resection is resorted to.

Eight cases with histories and plates are reported by the author, with the results to date.

W. P. HERBST.

A FUNDAMENTAL FACTOR IN THE RECURRENCE OF INGUINAL HERNIA—M. G. Seelig and K. S. Chouke

(Arch. Surg., November, 1923): Seelig and Chouke list as the essentials to a perfect cure, high sac ligation, restoration of the abdominal wall and primary wound healing. The first and last factor they dismiss with a word and go on to describe experiments designed to throw light on the possibility of complete and permanent restoration of the defective abdominal wall. This is usually attempted by suturing the internal-oblique and transversalis muscles and their conjoined tendon to the inguinal ligament of Poupart. The authors doubt if this procedure really accomplishes the intended purpose. Studies of fascia-muscle healing were carried out on dogs. A reduplicated edge of fascia lata was in each case sutured to the underlying muscles so that there was no tension on the suture line and that any separation could not be due to traction. Fifty experiments were carried out. In every instance where untraumatized muscle and fascia had been sutured together,

on healing the fascia was widely separated from the muscle to which it had previously been sutured. In every instance in which the muscle was traumatized by the excision of a wedge so that the fascia could be sutured in the raw trough, there was an attempt at direct union between fascia and muscle. This union was complete in only one instance. The authors conclude that attempted suture of muscle to fascia is inadequate and that to obtain good results one of the methods of uniting the fascia of the external oblique or the transversalis fascia to Poupart's ligament must be employed. The methods are those of Andrews, Pitzman, Harrison or Slattery.

DONALD K. BACON.

ACTINOMYCOSIS OF THE HEAD AND NECK. A REPORT OF 107 CASES: Gordon B. New and Fred Figi. (Surg., Gyn. and Ob., Nov., 1923.) Actinomycosis of the head and neck is probably the most commonly overlooked pathological condition occurring in this region. The infection is more common in males than in females, and may appear at any age. Seventy per cent of the patients reported were between the ages of twenty-one and fifty years. The activity of the disease bears no relation to the age of the patient.

All authors agree that actinomycosis occurs most frequently in the cervicofacial region. The 107 cases reported comprise 68 plus per cent of all cases of actinomycosis in the Mayo Clinic. Six cases of actinomycosis of the tongue were seen in the last three years and only 35 cases were found reported in the literature up to 1922.

The method of infection is very uncertain and different views are held by different investigators. Some contend that the infection is conveyed by direct contagion from cattle; others say that it is introduced by foreign bodies containing the organism; and still others hold that it is transferred by direct contagion from one human being to another. The organism has been demonstrated in carious teeth and tonsillar crypts of people with no demonstrable actinomycosis.

In this series of cases, 80 questionnaires resulted in finding that 56 per cent of the patients had not been in contact with the disease in cattle, and 43 per cent had been more or less closely associated with the disease in animals previous to the onset of their symptoms. Other facts are of importance, such as the presence of dental caries, picking decayed teeth with straws, or chewing bits of straw or grass.

"The clinical history of patients with actinomycosis of the head and neck depends on the virulence of the infection and the amount of secondary infection." The most common symptoms are stiffness, pain, and swelling in the region involved. The picture most common is that of multiple small draining abscesses.

Diagnosis must be based on the microscopic demonstration of the actinomycosis. The clinical picture and the presence of sulphur bodies help. Sulphur bodies are found most frequently in freshly opened pockets. Often it takes several weeks or more of observation to demonstrate the actinomyces microscopically and in 8 cases in this series the condition was not demonstrated microscopically. Actinomycosis of the tongue may simulate cancer, and infected cyst, or chronic cellulitis. Periosteal sarcoma must be

thought of and a list of conditions to be differentiated is given. "A tumor or gland of the neck or head which is clinically malignant, but does not prove so microscopically, is usually actinomycotic and further study of the issue may demonstrate this."

Of 85 patients, 70 per cent were well in from less than one year up to five or more years; 8.2 per cent were dead, and 21 per cent were under treatment. Six patients had meningeal involvement at the time of examination. One died from cancer which developed on an actinomycotic scar.

The best treatment to employ is drainage of abscess pockets and daily packing with iodoform gauze, radium, and iodides up to 200 grs. three times a day. The results from this treatment are very satisfactory and no patients except those with very advanced conditions with masses in the supraclavicular region, have had any extension develop in the chest.

W. P. HERBST.

HEMORRHAGE IN THE GENITO-URINARY TRACT

—William E. Lower (Surg., Gyn. and Ob., March, 1924): Hematuria from the genito-urinary tract is rarely alarming on account of the hemorrhage per se. However, it is a very important diagnostic symptom and should always be thoroughly investigated before a diagnosis of essential hematuria is made. Hematuria may be due to any of the following conditions:

(A) Outside the urinary tract:

1. Pathological conditions outside the genito-urinary tract.
2. Ingestion of certain drugs.
3. Acute and chronic febrile diseases
4. Scurvy.
5. Purpura.
6. Leukemia.
7. Pernicious anemia.
8. Septic infarct.
9. Aneurysm.
10. Syphilis.
11. Parasitic diseases.

(B) Within the urinary tract:

1. Bladder tumors.
2. Calculi urinary tract.
3. Renal tuberculosis.
4. Essential hematuria.
5. Cystitis.
6. Hypertrophy of the prostate.
7. Trauma.
8. Calculi in the bladder with hypertrophy of the prostate.
9. Carcinoma of the prostate.
10. Diverticula.
11. Hydronephrosis.
12. Cystic kidney.
13. Ulcer of the bladder.
14. Congenital deformity of ureters and kidneys.
15. Foreign body in bladder.
16. Papilloma of the urethra.
17. Strictures.

Tumors, tuberculosis, and calculi are the most frequent causes of hematuria, although some consider nephritis as first in importance.

Blood appearing at the meatus indicates a lesion anterior to the sphincter muscle. Blood at the termination of micturition is suggestive of a lesion within the urinary bladder. Blood in the semen suggests a lesion in the seminal vesicles or prostate. Blood after a renal colic suggests a lesion above the bladder. The source of bleeding is best discovered during a hemorrhage.

The author has charted 2,922 urogenital disease cases in respect to hemorrhage and lesion and concludes by saying:

"The above considerations emphasize the points that hematuria from the urogenital tract may be a symptom of almost any pathological condition within that tract and that therefore the presence of blood in the urine must be considered as an imperative indication for the application of every diagnostic measure at our command to locate the primary source of bleeding, and that no case should be classified as one of essential hematuria until every diagnostic measure has been applied without avail."

W. P. HERBST.

LATE ULNAR NERVE PALSY—Edwin M. Miller (Surg., Gyn. and Ob., January, 1924): Late ulnar nerve paralysis is peculiar in that it appears many years after the fracture. In nearly all cases the fracture occurs in childhood and usually between the third and fifth year. The usual type of fracture is one in which the external condyle is completely separated. Occasionally the site of injury has been at the internal condyle or in the supra-condylar region. Lateral and forward dislocation of the broken capitulum takes place and owing to inaccurate reduction non-union results, with a development of a cubitus valgus. The nerve is displaced from its bed as the olecranon process impinges against the medial condyle. This results in stretching and trauma to the nerve upon flexion. The paralysis in forty per cent of the cases occurred between 20 and 30 years after the fracture. It may begin as early as 3 or as late as 40 years after the fracture.

The methods of treatment are:

1. Cuneiform osteotomy to correct the deformity of the humerus.
2. Liberation of the nerve from its bed.
3. Transplantation of nerve in a new groove made by removal of a wedge-shaped piece of bone and lined with an aponeurotic-fascial flap.

The last method is the most popular method of treating the palsy. Ten case-records are given with illustrations and roentgenograms. Illustrations of steps in the operation of transplantation of the nerve to the flexor side of the elbow are given. As a prophylaxis against the development of the cubitus valgus deformity and the resultant ulnar nerve palsy an open operation with accurate fixation of the external condyle is suggested in those cases in which the external condyle cannot be accurately reduced by manipulation.

THE LIPOIDS OF MATERNAL AND FETAL BLOOD AT THE CONCLUSION OF LABOR—J. Morris Slemons and Henricus J. Stander (Johns Hopkins Hosp. Bul., January, 1923): This report is based upon work done to secure information regarding the activity of the placenta in the transmission of fats from the mother to the fetus. The author believes that the human placenta is impermeable to fats, as such. He refers to animal experiments of Ahfeldt which show that, after intensive feeding of fats, the fat-content of the maternal blood becomes ten times that of the fetal blood. Also the work of Gage and Gage, and of Mendel and Daniels, which indicate that the placenta is an effectual barrier to the passage of fat.

Their own work consisted of determinations of the fat-content of the maternal blood together with that of the fetal blood, taken at the time of birth. This shows a uniform finding of a higher percentage of fats and lipoids in the maternal blood. It was impossible to demonstrate any constant relationship between the fat content, and the character or duration of labor, the type of anesthesia, or other complicating factors. Their results show a complete independence of the two organisms as regards fat metabolism, and justifies the assumption that the fetal fat is synthesized from some material (probably glucose) which is freely supplied by the mother and which passes through the placenta.

As regards lecithin, the physiologic rôle of this substance is still unexplained. It possibly plays a part in the early stage of fat-metabolism. The author's studies indicate the same independence of the maternal and fetal circulations as regards lecithin content. The maternal lecithin increases towards the end of gestation, possibly as a preparation for lactation. The fetal blood plasma has a lower content, or about that of the normal adult.

The actual information concerning the significance of cholesterol is also meager. The cholesterol and lecithin seem to have certain antagonistic relationships, and are known to vary more or less simultaneously in amount. The increase of cholesterol may be part of a protective mechanism against an hyperlecithinemia. Although the concentration of cholesterol is never the same in the maternal and fetal bloods, the difference is neither constant nor characteristic. The authors have been unable to show any relationship between the cholesterol content and toxemia or eclampsia.

They conclude: 1. During the latter part of pregnancy, the fat, lecithin, and cholesterol content of the maternal blood increases, probably representing a preliminary step in the preparation for lactation. 2. The mother's blood contains much more of these substances than the

fetal blood does, and there seems to be a complete independence between the two organisms. 3. The placenta is impermeable to these substances. 4. Fetal fat then must be synthesized, probably from glucose, which is freely supplied by the mother in response to the demands of the fetus. 5. There is no characteristic change in the blood fat or blood lipoids accompanying the development of eclampsia or the allied toxemias.

ARCHIBALD L. McDONALD.

THE OCCIPUT POSTERIOR—P. T. Harper (Amer. Jour. Ob. & Gyn., Vol. 8, p. 53): The author presents this subject because he believes that no obstetric condition, which occurs as often, incurs more difficulties and responsibilities. It is pointed out that statistics based on examinations made at indifferent times during labor are valueless in determining the frequency with which the occiput, at the onset of labor, is directed posteriorly. The author insists that the primary position of the occiput is posterior in approximately 50 per cent of the cases. It is emphasized that the clinical course of labor can be correctly interpreted if certain fairly constant physical signs are remembered. The most striking physical characteristic of the child when the position is posterior is a varying degree of deflexion or bending backward of the presenting part, the mechanics of which is discussed in some detail. The result of auscultation and abdominal palpation are dependable as early physical signs: hearing the heart tones in one or the other flank, and palpating the small parts anteriorly. When the head has advanced to the middle of the pelvis in posterior positions, the cervix is further back and the anterior lower segment is more elongated than in anterior positions. The mechanics of anterior rotation of a posterior occiput are discussed, emphasizing the fact that the forces and conditions which interfere with anterior rotation are due to inertia of the uterine muscle, deflexion and to lack of tone of the pelvic floor.

Vaginal examination shows three points of clinical importance when the head is well down: first, presence of the caput forward of the occiput is evidence of deflexion characteristic of all posteriors and can be taken as a measure of it in the individual case; second, its location at one side or the other of the sagittal suture shows primary location of the occiput to have been toward the opposite side; third, thickness or depth of the caput can be accepted as positive proof of the amount of muscular efficiency actually expended in driving the presenting part downward.

Treatment is taken up minutely and the author's summary follows:

Until the shoulders have become engaged, treatment that displaces the child's body toward the front and holds it there favors assumption of an anterior position by the occiput, provided the presenting part is so located that the occiput can rotate. The latter may lie above or below but not in the inlet. After engagement of the shoulders, neither forward displacement of the body nor even manual rotation of the occiput gives hope of permanent assumption of an anterior position by the latter; for, when the rotating force is removed, the occiput reassumes its anatomical relation to the shoulders. When labor is obstructed at the inlet or in

the upper middle pelvis and the occiput is posterior, the conditions to be treated are those that have caused obstruction, such as retraction and pelvic deformity, and not posterior position of the occiput. In other words, there is no treatment for the occiput posterior as such when the labor is obstructed high up. When the presenting part rests in the low middle pelvis or at the pelvic outlet and when anterior rotation and subsequent advance do not occur, treatment depends upon analysis of cause or causes of delay, in the management of which the most important item is artificial aid in doing what nature is unable to do, in doing it in the way that most closely simulates nature, and in doing it before untoward results of delay demand it. The judicious use of forceps meets each of these requirements.

He concludes by recommending that the attitude toward occiput posterior should be one of active expectancy, that is, applying treatment which is indicated, but not meddling.

L. M. RANDALL.

THE PATHOLOGICAL ANATOMY OF THE CORPUS LUTEUM (ABSCISS, CYST, HEMATOMA, AND NEOPLASM)—Emil Novak and Richard W. TeLinde (Johns Hopkins Hosp. Bul., September, 1923): This report is based upon an examination of the pathological material in the gynecological clinic of the Johns Hopkins Hospital for the past few years. The authors suggest the following classification to cover the various changes which are to be observed in the corpus luteum:

I. The normal cycle: (a) Stage of proliferation. (b) Stage of vascularization. (c) Stage of maturity. (d) Stage of retrogression.

II. Physiological variations: (a) Cystic form. (b) Hemorrhagic form. (c) Corpus luteum of pregnancy (cystic and solid).

III. Pathological variations: (a) Corpus luteum abscess. (b) Corpus luteum cyst: (1) recent, (2) old. (c) Corpus luteum hematoma: (1) recent, (2) old. (d) Corpus albicans cyst. (e) Corpus albicans hematoma. (f) Combined types. (g) Corpus luteum neoplasm (luteoma).

IV. Allied conditions: Multiple "lutein" cysts of the ovary.

The normal cyclic changes in the corpus luteum are well described and illustrated and the significance of each is discussed, particularly the relationship of the vascular stage to hemorrhagic changes, and of the retrogression, to the corpus albicans.

Variations in the cyclical changes are not infrequent, and it is difficult to distinguish between those which may be considered as physiologic, and those which are definitely pathological. Some consider all cystic forms as abnormal but the authors class as pathological only those which are larger than the normal ovary. Lutein cells showing more or less evidence of degeneration are to be found conspicuously in the cyst walls. Hemorrhage into the corpus luteum during the vascular stage is common, and the distinction between physiologic and pathologic types is not clearly defined. The corpus luteum of pregnancy is larger than that of menstruation and is more likely to be cystic. The latter type is found more often in cases of ectopic gesta-

tion. Hemorrhage is not uncommon in the corpus luteum of pregnancy, and there is a more complex organization of the fibrous structure.

Pathological variations: Abscesses have been frequently described. They are more likely to develop in the cystic or hemorrhagic forms, and are often associated with inflammatory pelvic lesions. The wall of the abscess shows the typical yellow color with inflammatory infiltration. They divide the corpus luteum cysts into the recent and old, which represent different stages of the same process. They consider as pathological those which exceed 2 c.m. in diameter. They are likely to be associated with abnormalities of pregnancy, pelvic inflammatory disease, or fibroids. There was little or no associated menstrual disturbance. The question of Corpus Luteum Persistens is discussed at some length, particularly in regard to its effect upon menstruation, and sterility. They believe that many of the reported cases are actually due to an unrecognized pregnancy, as may be proven by microscopic study of the endometrium.

The hematomas are relatively common, but there is no absolute distinction between the abnormal and normal types, except size. Most of their cases were associated with pelvic inflammatory disease which must be considered as a causal factor. They are classed as recent or old, depending upon the structure of the wall. As regards the neoplasm, the authors make no very definite statements. The article gives a comprehensive review of this subject and is worthy the careful study of all who are interested in the pathology of the corpus luteum.

ROY N. ANDREWS,
MANKATO CLINIC, MANKATO

A STUDY OF THREE HUNDRED CASES OF PERTUSSIS IN A HOSPITAL—Charles Herman and Thomas Bell (Arch. of Ped.): 1. Females are more frequently affected with pertussis than males.

2. Eighty per cent of all cases of pertussis occur in children under 5 years of age.

3. The largest number of cases of pertussis occur during the summer months, at a time when the other communicable diseases are at their lowest point.

4. Every spasmodic cough is not whooping-cough. There are cases of pseudo-pertussis. The term pertussis should be restricted to an acute infectious and communicable disease, caused by the Bordet-Gengou bacillus.

5. The Bordet-Gengou bacillus is regularly present in the catarrhal stage of the disease.

6. Pertussis is most communicable in the catarrhal stage, when its true nature is not recognized. It is usually not communicable after the fourth week.

8. The respiratory complications are by far the most important. They are present in 58 per cent of the series. Fourteen per cent had a complicating bronchopneumonia.

9. The earliest and most characteristic change in those patients who have bronchopneumonia is the presence of localized fine resonant râles at the base or at the angle of the scapula, especially on the left side.

10. The susceptibility and unfavorable course of pneumonia in infants is probably due to immunologic, not to anatomic peculiarities.

11. There is no conclusive evidence that pertussis is an important factor in the causation of pulmonary tuberculosis. A positive Pirquet reaction does not become negative in the course of pertussis.

12. The principal aids in the early diagnosis of pertussis are the presence of a relative and absolute lymphocytosis in the blood; the presence of the Bordet bacillus in the sputum; and a positive complement fixation test. The cutaneous tests have not proved of any value.

13. The prognosis in pertussis depends on the age of the child, and on the presence or absence of pulmonary complications.

23. In the control of the spasmodic cough, antipyrin fortified by bromides has given the best results. We have not obtained favorable effects from injections of ether, or from vaccination.

24. Pertussis vaccine has a specific effect in about one-fourth of the cases. In those which fail to respond to treatment, the vaccine may be given too late or they may not be due to the Bordet bacillus.

R. N. ANDREWS.

PRELIMINARY REPORT ON THE TREATMENT OF PERTUSSIS BY THE X-RAY—Henry I. Bowditch and Ralph D. Leonard (Boston Med. & Surg. Jour., March 8, 1923): Twenty-six cases of active pertussis received X-ray treatment. The patients were from three months to forty years of age and were ill from one to ten weeks. Each patient received three or four x-ray treatments, at intervals of two to three days; the dosage was regulated according to the age of the patient, and the total amount of the X-ray given any one patient was well under an erythema dose. About ten per cent were prompt cures, spasms and cough disappearing entirely after two or three treatments; in a period of six days seventy per cent showed a very definite improvement, the number of paroxysms being much diminished to one or two a day, during a period of seven to ten days.

Ten to fifteen per cent showed no apparent benefit. The treatment at present is wholly empirical but the authors believe it may prove to be of more value than any other form of treatment.

THOS. MEYERS.

USE OF X-RAY IN TREATMENT OF PERTUSSIS—H. I. Bowditch (Boston Med. and Surg. Jour., Sept. 6, 1923): Three hundred and fifty cases were treated with the x-ray, the first three exposures at two-day intervals; if more were needed, they were given at intervals of a week, following the first three. Exposures were made alternately on the anterior and posterior aspects of the chest,

with clothes on, with the tube 26 inches away. Filter A was used, with 12 to 16 milliamperes from three to four minutes. Shorter treatments were given for children under eight months.

The results in the majority of cases were: eight hours after exposure the cough became softer and less frequent, vomiting and convulsions stopped, and the children slept. Sixteen hours later the cough became more characteristic, but vomiting and convulsions did not reappear. Subsequent treatment had similar effect.

One or two months after treatment the mothers reported 75 to 100 per cent improvement. Some found no relief; there was no absolute cure.

The treatment should be used in conjunction with vaccine.
THOMAS MEYERS.

THE TREATMENT OF WHOOPING COUGH IN PRIVATE PRACTICE—Wm. C. McKibben (Boston Med. & Surg. Jour., Sept. 6, 1923): Records were kept of all phases of treatment as applied in an extensive epidemic beginning in 1919. Response to treatment was better among the more well-to-do patients, where segregation and re-infection were much less, and intelligent co-operation could be better carried out than in the thickly populated foreign quarter.

Auricchio of Rome in January, 1923, published observations made on the blood of ten children who were given pertussis vaccine; these showed marked improvement in the opsonic index fairly early, while the complement fixation test did not show immunity developed until the third week of the treatment. This indicates why immediate improvement by vaccine does not usually result.

McKibben uses fresh plain or combined pertussis vaccine, injecting it deep intramuscularly into the buttock at intervals of two days. The initial therapeutic dose was one billion; the second dose, two billion; the third, four billion and the fourth dose five or six billion. Occasionally one or two more doses of equal size were necessary. Even eight or ten billion were given in older children with safety.

The duration of the disease and the severity of the symptoms were usually reduced, and the complications were much less frequent, following vaccine treatment. Infants seemed to respond to it better than older children.

Drug therapy gave the usual disappointing results.

THOS. MEYERS.

THE DIAGNOSIS OF ENLARGED THYMUS BY THE X-RAY AND TREATMENT BY X-RAY OR RADIUM—G. E. Peahler (Arch. of Ped.): Thymic enlargement is receiving more and more attention throughout the country. The roentgen ray is undoubtedly the most reliable means of diagnosis, and radiation by x-ray or radium is a specific in treatment. So general is the response to treatment, that if the symptoms do not show definite improvement after a few x-ray treatments or one radium treatment, the diagnosis is almost certainly incorrect, or the symptoms are influenced by some associated pathological condition. The classical symptoms are dyspnea, cyanosis, and an inspiratory stridor. The chief complaint is nearly

always cough or attacks of choking, which come and go, appearing frequently in paroxysms. It is conceivable that the thymus might be enlarged in thickness and not in breadth. Most of these moderate grade shadows in the upper mediastinum are due to lymphadenitis rather than to enlarged thymus. Both thymic enlargement and lymphadenitis yield to x-ray treatment. Examine the child while crying, because it is while the child cries or struggles that the thymic symptoms develop. Use a 9-inch spark-gap, 5 ma. at a focal skin distance of 30 cm., for 15 or 20 minutes, with rays filtered through six millimeters of aluminum. One may use a 9-inch gap, 5 ma. 3 mm. aluminum filter, 10-inch distance, with 3 minutes' exposure for the new-born and 5 minutes for older children. Treat the patients once in four weeks; three to five treatments should be sufficient. Heublein uses the radium in capsule with 0.5 mm. silver for filter, wrapped in gauze so that when strapped to the chest by a strip of adhesive, it will be a half-inch from the skin surface. Four marks are made in the form of a rectangle over the thymic area and the nurse is instructed to allow the package of radium to remain 2 hours over each area. This makes a total exposure of 800 milligram hours.

R. N. ANDREWS.

RESULTS OF ACTIVE IMMUNIZATION WITH NEW MIXTURE (1/10 L PLUS OF TOXIN-ANTITOXIN) TOXIN-ANTITOXIN IN PUBLIC SCHOOLS—A. Zingher (New York State Jour. of Med., Feb. 1, 1924): Zingher finds that the administration of 1/10 L plus mixture of diphtheria toxin-antitoxin produces an active immunity in a large percentage of children. The conclusions are that the 1/10 L plus toxin-antitoxin mixture is the best type of mixture to use for active immunization against diphtheria. The local and constitutional reactions with this new type of mixture are very slight and compare favorably with those noted for the older type of toxin-antitoxin mixtures containing 3-5 L plus doses per cubic centimeter. The 1/10 L plus diphtheria toxin-antitoxin may be administered to infants and older children without fear of any marked local disturbance. Three doses of 1 c.c. each are given intramuscularly at intervals of from seven to ten days. The immunization following the administration of this 1/10 L plus diphtheria toxin-antitoxin is not established until three to six months after its administration.

C. A. STEWART.

THE RECTAL ADMINISTRATION OF NEOSALVARSAN IN CHILDREN—F. Fortunata (Arch. of Ped., Dec., 1923): It is necessary to know the technique used by Modigliani for the successful injection of salvarsan in the rectum: 1. With a soft catheter he washes the rectum until the water returns clean. 2. Ten minutes before the injection of neosalvarsan, he introduces into the rectum 10 c.c. of water with 30 drops of cocaine (1 per cent), and two drops of tincture of opium to anesthetize the rectal tract which must retain the solution of neosalvarsan. After the injection of cocaine, the catheter remains in place and the outer end is closed with forceps for ten minutes; after which, the forceps are opened, and the excess cocaine is let

out. 3. Through the same catheter, 10 c.c. of double distilled water and gm. 0.15 neosalvarsan with 2 drops of tincture of opium are injected into the rectum very slowly during the child's nursing. The nursing is to prevent the infant from crying. The author found the use of cocaine unsatisfactory in these cases, but concluded it was better to stop all nursing for eight or ten hours previous to the injection, giving the child, however, small quantities of light cereal-water every two hours. The treatment with arsenobenzol is very efficacious in hereditary or acquired syphilis in children. Compared with the mercurial treatment it hastens the disappearance of the syphilitic manifestations. The administration of the arsenobenzol by rectum in infancy has the advantage over the intravenous treatment in that it is readily applicable and more practical. In order to be effective, it is necessary to administer a cycle of rectal injections, varying from five to seven days. The medicine should be injected in increasing doses as follows: minimum 10-15 c. gm. per dose; maximum 60 c. gm. in children under one year. It is necessary to proportion the dose to the weight of the body.

THE SPACE-COMPENSATING FUNCTION OF THE CEREBRO-SPINAL FLUID—ITS CONNECTION WITH CEREBRAL LESIONS IN EPILEPSY: Walter E. Dandy. (Johns Hopkins Hospital Bulletin, August, 1923.) In a series of operations for the relief of epilepsy, a number of changes were found with considerable uniformity. These were: (1) dilatation of ventricles, (2) collection of fluid on the surface of the brain, (3) pockets of fluid in the brain substance, (4) softening of the brain in association with these collections of fluid, (5) areas of induration in the brain, (6) changes in the meninges, and (7) congenital malformation. It is believed that these are evidences of actual cerebral lesions (end-products of repair), and the frequency of the findings leads to the conclusion that there is a pathological basis for so-called idiopathic epilepsy in a large proportion of cases. Confirmation of this view is obtained by means of ventriculography, which in a certain proportion of cases shows acquired or congenital distortion of the ventricles. A more detailed study of the lesions will be made at some future time.

C. A. STEWART.

OBSERVATION ON THE TREATMENT OF SCARLET FEVER WITH SCARLATINAL ANTISTREPTOCOCCIC SERUM—Francis G. Blake, James D. Trask and John F. Lynch (Jour. of the A. M. A., March 1, 1924): These investigators find that the anti-scarlatinal serum prepared by Dochez by the immunization of a horse with the scarlet fever streptococcus possesses the capacity to blanch completely and permanently the exanthem in a local area about the site of intracutaneous injection in patients having scarlet fever. This property is apparently specific for this serum and therefore is undoubtedly of diagnostic value. In addition the serum apparently possesses very marked curative properties. In twelve early cases of scarlet fever, five of which were severely toxic, administration of the serum was followed by rapid and complete recovery in

twelve to thirty-six hours. In the majority of cases a single intramuscular injection of forty to sixty c.c. of serum was given. In two very toxic cases approximately two hundred c.c. was required.

C. A. STEWART.

THE USE OF SALICYLATES PER RECTUM—George R. Irving (Arch. of Ped., Dec., 1923): The method of giving salicylates per rectum, while not a new one, was taken up in an attempt to find a more generally satisfactory way of administering this drug. At one time it was thought that it would be a fair way of prescribing the amount to be used to allow one grain per body pound weight, but he has since used in certain instances, and with safety, a grainage almost three times the body weight of certain of our patients, so that at the present it is impossible to state a rule as to dosage. The average dose has ranged from 20 to 100 grains. The author advises the use of a "baby bulb syringe," sometimes called the ear syringe, for use in administering an enema to an infant. Use plenty of vaseline about the anus and on the syringe tip in order that as little irritation as possible will be experienced in slowly introducing the inch and a half of nozzle. It is a standing rule that the rectal administration be attempted only after one hour has elapsed from the time of the movement of the bowels. He has taken the stand that the injection be held in at least one hour for its absorption, so that if expulsion has taken place within this time, he urges that the process be repeated. Salicylate in the form of sodium salicylate may be conveniently administered per rectum. Administration may be considered safe in the hands of an attendant with ordinary intelligence or without special training. Relatively large doses may be given once or twice daily. By this method of administration the stomach is particularly free of irritation.

THE CUMULATIVE EFFECT OR SUMMATION OF X-RAY EXPOSURES GIVEN AT VARIOUS INTERVALS: Warren and Whipple. (Jour. Exp. Medicine, Dec., 1923.) In previous papers these authors have detailed their experimental methods, which consist of giving large doses of x-rays over the abdomen of dogs, producing a marked lesion in the intestines and stomach. The average maximum sublethal dose for dogs was divided into a number of fractions which were administered at different intervals. By varying the interval and the dosage they were able to determine the following facts:

1. One large dose causes a definite injury to the mucosa of the small intestine and the severity of the clinical intoxi-

cation parallels the extent of the injury. The intoxication lasts 4 to 6 days if the dose is sublethal.

2. Small, repeated doses within the 5 or 6 day period will cause practically the same cell injury and clinical intoxication as a single dose equal in size to the sum of the small doses. Doses given at an interval of more than 6 days do not show this summation but, in fact, in one experiment seemed to show some increased tolerance.

3. These results are markedly different from the cumulative effect upon the skin especially as expressed by Kingery's formula. In view of the fact that the intestine in its position is comparable to deep-seated tumors, it would seem reasonable to use the evidence adduced from these experiments as an index to the effect of x-ray dosage upon tumors, rather than to use the effect upon the skin.

LEO G. RIGLER.

ANATOMO-RADIOLOGICAL STUDY OF THE MEDIAN CARDIO-VASCULAR SHADOW AS SEEN FROM THE FRONT—L. Delhern and Robert Chaperon (Jour. de Radiologie et d'Electrologie, January, 1923): Until recently most of the classical descriptions of the radiologic appearances of the mediastinal cardio-vascular shadow have led us to believe that the right side of this shadow is produced from above downward by the ascending aorta, the superior vena cava and the right auricle; the majority of radiologists believing that the aortic shadow projects to the right beyond that of the vena cava. The left side of this cardio-vascular shadow was thought to be made up, from above downward, of the arch of the aorta, the pulmonary artery, and the left ventricle of the heart. By some the aortic hemicircle was considered to represent the descending portion of the arch and by others the first portion of the descending aorta.

The object of the authors of this valuable contribution was to attempt to dissociate the various elements in the composite shadow representing the cardio-vascular mass as seen from the front. They first made radiographic studies of the thorax of each cadaver *in statu quo* and then proceeded to render opaque the more important structures entering into the formation of the mediastinal cardio-vascular shadow. It was essential to avoid altering the relations of the mediastinal contents, and they therefore accomplished their object by injecting baryta milk through the inferior vena cava from below the diaphragm without disturbing the thorax in any way. The study was repeated on 14 subjects of different ages, and more than 175 radiographies were made.

The more important results are as follows: with respect to the formation of the right border of the median shadow, comparison of the radiographies made before and after opacification disclosed the fact that the upper part of the shadow is produced by the superior vena cava and the right brachio-cephalic venous trunk. Point D represents the termination of the right border of the superior vena cava at the right auricle. Point D¹ corresponds to the outer edge of the orifice of the inferior vena cava in the right auricle. According to the descriptions of anatomists the ascending aorta lies in the median line almost entirely hidden behind the sternum. From a study of the injected aorta in eight subjects it appears that the normal ascend-

ing aorta does not project to the right perceptibly beyond the right border of the sternal serrations or beyond the right margin of the spinal column, and in three subjects the right border of the ascending aorta did not pass to the right beyond the median line; therefore the ascending aorta does not form the right border of the cardio-vascular shadow, which is, in fact, produced from above downward by the right brachio-cephalic venous trunk, the superior vena cava and the right auricle; the aorta always lying well within the vena cava. The experiment was repeated on young subjects as well as on very old subjects in order to determine if the senile aorta can overshadow the vena cava and appear to the right of it, but, under normal conditions, even the senile aorta never projects beyond the right border of the superior vena cava, and, therefore, plays no part in the formation of this side of the cardio-vascular shadow.

With reference to the left border of the mediastinal shadow there has been considerable divergence of opinion even among anatomists, particularly about the aortic arch. Some claim there is no such thing as a descending portion of the arch and call it the first portion of the descending or thoracic aorta. According to Delherm and Chaperon the aortic hemicircular shadow is caused by the terminal portion of the arch. Above the hemicircle the upper limit of the left border of the median shadow is due to the sterno-vertebral shadow, but may exceptionally be produced by the projection of the subclavian artery in the first left interspace.

According to them the middle arc of the median shadow on the left side represents, under normal conditions, the profile of the pulmonary artery. However, in two cases in which the heart was large and transverse, the middle arc projected beyond the pulmonary artery and they feel obliged to conclude that the left margin of the pathologic auricle may take part in the formation of this border. To settle this point they injected primarily the aorta (always from below and without opening the thorax) and the left side of the heart; and secondarily the right side. They were thus able to convince themselves that the pulmonary artery projects considerably beyond the descending aorta and that it constitutes by itself the middle arc of the shadow on the left side. However, this experiment was carried out but once and they feel that it will require confirmation by clinical means. The upper border of the median shadow

is produced by the left brachio-cephalic venous trunk which joins the aortic hemicircular shadow below. They found it uniformly impossible to render the auricles sufficiently opaque to allow of accurate study.

BOOK REVIEWS

BOOKS RECEIVED FOR REVIEW

SEXUAL PROBLEMS OF TODAY. William J. Robinson, M.D. 12th edition. 340 pages. New York: The Critic and Guide Company, 1923. Cloth, \$2.00.

HIGH FREQUENCY ELECTRIC CURRENTS IN MEDICINE AND DENTISTRY. S. H. Mouell, M.D. 465 pages. Illustrated. New York: William R. Jenkins Co., 1923. Cloth, \$4.00.

PRACTICAL ELECTROTHERAPEUTICS AND DIATHERMY. G. Betton Massey, M.D., Fellow and Former President American Electrotherapeutic Association; Member Philadelphia Obstetrical Society, etc. 402 pages. Illustrated. New York: MacMillan Company, 1924.

DISEASES OF THE SKIN: Frank Crozer Knowles, M.D., Professor of Dermatology, Jefferson Medical College, etc. 2nd edition, thoroughly revised. Lea and Febiger, Philadelphia and New York, 1923.

The number of text-books on Dermatology by American authors at the present time, compared to those of twenty years ago, has grown considerably.

Among those appearing in later years, that of Knowles stands out as a very useful and, for its size, a very comprehensive work.

While there has been considerable advance in knowledge in recent years in respect to diseases of the skin, there is unfortunately much still obscure both as to etiology and treatment. The reader, however, of this book will find the latest information on the subject concisely and clearly stated.

The work is well illustrated and the number of illustrations we have in this issue which are not in the previous one certainly adds to its attractiveness. The reviewer feels that the book may be recommended to all who wish a concise, practical and sound work in dermatology.

J. M. ARMSTRONG.

Mrs. Christine Lund of Hutchinson, Minnesota, offers for sale complete office equipment of the late Dr. Theo. C. Lund, physician and surgeon. Surgical instruments, scales, safe, desk (McCaskey's system), sterilizer, etc. Equipment in good condition. For information inquire of Citizens Bank, Hutchinson, Minn.

GOOD OPENING for physician at Brownton, Minnesota. For information, address B86, care MINNESOTA MEDICINE.

\$12,000 MISSOURI PRACTICE FREE—Wonderful location. General practice. 95% collections. Good opening for small hospital. Overwork cause of sacrificing proposition. Buy office effects and take practice. Address B80, care MINNESOTA MEDICINE.

FOR SALE—To close an estate, good location for practice in St. Paul. No other physician in same vicinity. Excellent opportunity; will bear close investigation. Address B75, care of MINNESOTA MEDICINE.

CLINICAL CONTRASTED WITH INSURANCE OPINION OF AN INSURANCE APPLICANT*

J. ALLEN PATTON, M.D.

Medical Director, The Prudential Insurance
Company of America
Newark, N. J.

The word clinical means, in its restricted sense, the observance of the symptoms and course of a disease as distinguished from the anatomical changes. The clinician or practicing physician, differing from the pathologist or laboratory man, does much more than this, for he sees his patients at the home or in an office, a dispensary or a hospital. He obtains the previous health history, usually from a willing and helpful patient; he makes whatever physical examinations are necessary or that the facilities at hand afford; he notes the appearance and records the anatomical or physical changes found; he adds the results of the available indicated laboratory tests; he sees and re-examines his patients more than once, often repeatedly; he refers to his text books and journals and frequently obtains consultation; he applies treatment of various kinds, watching the effects; he makes his diagnosis and prognosis and these, with the treatment, as we all know, may change from time to time for various and justifiable reasons.

The prognosis is of two degrees or kinds, immediate and remote. Will the patient recover from the present attack completely, or will his recovery be incomplete with more or less, permanent ill-effects upon his health? Will he have a slow or delayed, but ultimate full recovery? Here again the clinician has the advantage of repeated observations or examinations and almost unlimited time in which to reach a conclusion and give his opinion.

During all this it is to be remembered that the patient is doing all he can to aid his physician.

The insurance examiners—and the best of these are found in the ranks of good clinicians in the everyday practice of medicine and surgery—meet an entirely different situation. We will all admit that the ideal place for an insurance examination is at the examiner's office, but this cannot always be arranged and it is needless to recount here the reasons why.

Thus many times the examination has to be made in noisy, unsuitable surroundings. There is no privacy, he is unable to remove sufficient clothing to permit of proper chest or abdominal examinations and he cannot verify the weight. There is insufficient time, because the applicant is too busy or has not been sufficiently sold by the soliciting agent.

Additional to these difficulties, though many applicants tell all they know about their previous health history or their present signs or symptoms, thereby aiding the medical examiner to furnish a pen picture, together with his own conclusions, there are, unfortunately, all too large a number who use their intelligence to the limit to prevent the examiner from learning about any previous conditions that might have unfavorable effects upon their obtaining the insurance requested, and numerous others in some manner have discovered methods of temporarily relieving or causing to disappear signs and symptoms that might give rise to an unfavorable opinion in their case.

We can, therefore, all of us, readily see that the insurance examiner, in the short time he is allowed in which to make his examination—often in inconvenient and unsuitable surroundings and frequently without the aid, if not with the direct antagonism, of the applicant—has a much more difficult problem than the clinician to obtain and set down in connected form the information for a case history. Those supposedly healthy or well are probably the only ones who unreservedly submit themselves for insurance examinations.

*Read at Fourth Annual Clinic Week, Ramsey County Medical Society, St. Paul, January, 1924.

The expert or well-trained clinical diagnostician will find early or prodromal signs that might escape the general practitioner; but the latter, who has been endowed with good general common-sense and has trained his powers of observation along physical examination lines, will usually recognize significant changes even in their incipency.

Inspection or observation is one of the most essential features in the training of both clinician and insurance examiner, and the best results are obtained by those who have best developed this faculty.

Personal knowledge of the applicant or his family and his living conditions should aid the examiner in his report and, be it said to his credit, the honest physician responds to the trust placed in him by the company for whom he is rendering a report.

Honoring, as I do, and as any reasonable individual must, the sacredness of the trust imposed upon a physician in his dealings with a patient, is there not a still more sacred duty imposed upon the profession when the question of the greater good to the many opposes that of the individual? An applicant for insurance, be he examined by his personal physician, an acquaintance or a stranger, by that application agrees to give such information as he is able, and when he states that he has been under the care of or received advice or treatment from a physician, he, by that admission, has released that physician from his personal obligation. Therefore, I would prefer in the average case to have the examination of the average physician who knows the applicant to that of the higher-trained man to whom the applicant and his personal history are unknown. The questionable applicant (probably one in four) who may try to conceal his history or physical abnormalities, can undoubtedly be best examined by the best trained physician so far as physical examination and diagnostic conclusions are concerned.

Insurance medicine is founded upon case histories (personal and family records), physique (height, weight and trunk measurements, with changes in weight), age, occupation, race, sex, marital state and physical and laboratory findings. The Home Office Medical Department must take these records, study them carefully and place the applicant in a group made up of as nearly similar individuals as they can, and from the results obtained by insuring previous individuals in such a

group estimate the probable longevity or give the insurance (remote) prognosis or the effect upon the length of life.

Briefly, we might state that insurance premiums are based upon actuarial calculations as to the amount of money (premiums) that must be collected during the estimated length of life of the individual to enable the company to pay the expenses incidental to obtaining the application, making the examination, issuing the policy, supervising the business and paying the claim. Based upon normal death rates for various ages, the deaths per year are calculated for groups of a thousand and confirmed by many thousands. Some members of these groups die early, or before the expected period, and some outlive that time, hence the average. Variations from the average, due to variations from normal health histories or physical findings, make necessary various types of policies differing from the regular or standard policy, and in those that cannot be classified or that cannot be covered by a reasonable rating a rejection must be made. The group basis, therefore, must supplant the individual in insurance prognosis and thus another difference arises from the clinical viewpoint. The mathematical accuracy of the study that has been made of life insurance records has enabled the companies to offer, during the last few years, insurance to many an individual for whom no adequate rate had been made and whose insurance would, therefore, have been at the expense of the standard risk, or he would have been declined.

We find that many of the differences that exist, start from the practical everyday experience of the practitioner with his patient as contrasted with what the future has in store for that patient, based upon life insurance records of their experience with the large mass of people the companies have on their books.

Occupation is healthy or unhealthy in the minds of the average man as he sees the effects upon his acquaintances or neighbors or as he may occasionally read a newspaper or magazine article. Quite general, but indefinite, ideas prevail about the increase above the normal average of a community of impairments or deaths that are due to the iron and steel mills, mining (coal and metal), lumbering, railroading in its various branches, textile mills, hat factories, duties of peace officers, or hundreds of other occupations. All these have had their records kept and estimations have been made show-

ing how they compare with the average death rate, and insurance is granted accordingly—not upon the individual case.

The medical knowledge of the field examiner is needed to recognize and record any changes from the normal that he detects and the effects of these changes must be considered with various other features in the insurance summation.

Consideration of the habits of an individual in insurance was ordinarily limited to the use of alcohol of the ethyl chemical type and the effects of varying amounts used intermittently or daily, slightly or to intoxication, had been quite well determined for insurance purposes if not from the ordinary physiological or pathological standpoints. Agreeing that the differences in individual resistance are probably shown as well in the effects of alcoholic beverages as of anything else, still the mass results from histories recorded cause the classification into insurable or not insurable, and the exceptions cannot be made that the clinical observer thinks should be. The effects of modern intoxicating liquors are better known as yet from individual instances, but present indications are for worse effects than formerly.

Family history plays an important part in life insurance. No matter how much we may read or think pro or con on the subject of heredity, each of us sees every day children who show enough of the ancestral characteristics to make us believe there must be inherited disease tendencies as well as mental and physical traits. Thus the histories of apoplexy, paralysis, circulatory diseases, diabetes, tuberculosis, early deaths and many other points in the family history all call for care, either because of these records alone or in connection with personal health history or the physical findings.

Personal health histories have their value increased by family histories, age, sex, occupation, physique and the examiner's physical findings.

We are all aware of the possibilities of serious developments after slight superficial injuries, mild colds, digestive upsets, etc., and while the probable effects are usually belittled to the average patient the true physician also cautions his patient to take common-sense care of himself until the mild ailment has disappeared as most of them do. Life insurance cannot disregard the presence of these abnormalities because of the occasional case that goes wrong; hence, as a rule, final action is deferred until receipt of an examiner's statement that

full recovery has resulted, or approval may be taken requiring a favorable health certificate before the policy can be delivered.

Statements of present conditions should not be vague or diffuse, but must be definite enough to enable the medical reader of the case history to formulate a legitimate opinion based upon ordinary medical practice, supplemented by his training in the use of insurance standards. Such a statement as "cold for the last two weeks" may mean nothing of any moment to the examiner and it may mean any of numerous possibilities to the home office reviewer. Serious illnesses or surgical conditions present, or histories of such past troubles, call for rejection, postponement, or an action depending upon their character or severity and the prognosis of the immediate and ultimate outcome. This statement from an examiner of large experience: "Cystoscopy showing irritation of one kidney? Cured by large quantities of water," may have been sufficient for him with his other knowledge of the case, but we were not furnished dates, symptoms, duration of treatment, microscopic urinalysis, etc., and, therefore, had insufficient information to form an opinion on the future of the individual. A report received in December, 1923, of "Gallstones and drainage in 1921, prompt recovery and all right since," would do for a medical or surgical opinion for the immediate future, but clinical and insurance experience shows that the probability of recurrence of gall stones or gall bladder troubles is based upon the time since symptoms or operation. What month in 1921 did this operation occur? If in January then practically three years had elapsed by December, 1923, but if in December, 1921, only two years had passed. The clinical examiner found the case all right but he failed to complete the history for use of his medical director. Such instances could be multiplied indefinitely but they would only serve to emphasize the insurance need of enough facts to give a proper picture of the applicant, thereby allowing legitimate application of medical life insurance experience in the proper placing of the individual case.

The reported physique of an applicant is one of the chief troubles of the home office, and yet it should be one of the easiest parts of an examiner's report to record the figures so that there could be no doubt. Weight in ordinary street clothes, minus overcoat, height in ordinary street shoes, and chest and waist measurements under the vest should be

readily and accurately obtained. The only figures about which there might be any uncertainty are those for weight, as scales are not always at hand.

Mortality According to Height and Weight

Here, if there is any doubt in the examiner's mind, or if the case is materially below or above average weight, special comment should always be made to show that the examiner has noted the abnormal weight.

Physicians, because of their professional training, are quite positive usually of the results of their personal observations. All will admit that overweight is an impairment, that abdominal girth greater than expanded chest is a handicap to long life, that soft or flabby flesh is not a good sign, yet we each know of so many persons of these types that live to old age that we are prone to disregard them in practice and only strive in a half-hearted way to instruct these persons in improving their physique, unless some direct complaint is

traced to this as a cause. Height and weight taken in connection with age have probably more definite data than any other phase of insurance selection, hence there is here a sound foundation for action. Year by year of age and almost pound by pound of weight the records have mounted so that the classification can be made with great exactness.

The accurate verified height and weight is, therefore, most important in any case more than 20 per cent over or under the average for age. Group classes must be formed and even 1 or 2 pounds may mean the difference between standard or rated insurance or a rejection.

The American Experience Table of Mortality gives, for a given age, the number of deaths that are expected per 1,000 during the next year. Any increase over this expected number means an unestimated loss to the insurance company, unless their policy has been issued to cover such an increase.

The effect of age upon height and weight can be illustrated by taking the two groups of 20 to 24 years and 40 to 44 years, as shown in the chart.

Height makes a difference, the greater mortality rate being shown by the taller persons. Those under 5 ft. 7 in. show a lower and those over 5 ft. 10 in. a higher mortality. A brief glance at the table below should convince anyone that insurance must take account of age, height and weight in the calculation of a premium rate. Mortality percentage as compared with 100 per cent is calculated.

Very frequently reports are received that the applicant has occasional digestive (gastric, intestinal or biliary) disturbances, but that they do not keep him from his occupation for more than a day or two; there may be a rheumatic history without definite symptoms or the statement that it was articular in type; attacks of disturbed breathing upon slight exertion; of rapid heart action or palpitation; of feeling tired after ordinary or regular daily routine; slight loss of weight without climatic or

occupational cause; pleurisy may be mentioned but no particulars given; suspicious of specific infection with history very indefinite, etc. Such cases are very often properly rated by the examiner as first-class so far as his findings at the time of examination are concerned and he frequently so informs the applicant and many times the interested agent; but, lo and behold, a request comes from the home office for more information or, in some cases, the application is declined or a policy offered with an increased premium.

The insurance case requires definite records of parts of the body affected, primary and secondary, the date or dates of attacks, duration of illness or period in bed or house and the following stage of convalescence, severity of symptoms, complications present and degree of recovery. Acute attacks, from which recovery is usually prompt and complete, are much more preferable in life insurance work to indefinite or chronic indispositions, whose histories are often incomplete but whose causes are hard to determine and are frequently of serious systemic character. These indefinite recurring mild indispositions are warning signs in insurance selection and should be in clinical or practical medicine, especially after age 45 to 50 has been attained. Here lies the field of preventive medicine and the physician can do much for the health of his local community, his state and his nation, by preaching and practicing regular physical examination of his patients, to be followed by sensible regulations of work, diet, rest or recreation for those showing indications of feeling the strains of life, and the recommendation of medical or surgical treatment for those needing the same. Most physicians would find their incomes as large as at present, but it would come from a more satisfied clientele for they would have been kept well instead of being treated after becoming ill. In our opinion, the periodical health examinations being offered by insurance companies to their policyholders—as in the Prudential Longevity Service—can be made most effective by working with the policyholder's own physician, for thus he is kept in touch with the doctor, who has more personal interest and who is able to extend advice and supervise treatment that will benefit the individual the most.

Some of those present will recall the results of a study made a few years ago of the Mayo Clinic digestive ulcer cases. These showed better results for duodenal than gastric operations after the sec-

ond year and until the sixth year, when the mortality was found to be practically the same as for persons of the same ages without any such operations. We are receiving many applications from ulcer cases (medical and surgical) and they are almost all reported in first class condition of health, but we cannot insure them at regular rates unless in our opinion sufficient time has elapsed. The number of these cases we have taken during the last three years indicates that after five to ten years' experience we can tell more of the remote prognosis in the average case than we are in a position to do now. This information will be of service to the general physician for many of the cases being insured were treated by him and not in our large surgical hospitals or centers.

Syphilitic infections are so prompt in the disappearance of cardinal secondaries under modern treatment that more histories of doubtful character are received than formerly, but advantage must be taken of suspicious cases, for past records show a large mortality in such cases presumably because treatment was discontinued too soon. Treatment with salvarsan or its similars, followed by mercurials, is considered the legitimate method and a Wassermann check is advisable from time to time, especially if any obscure train of symptoms arises. Such a course of treatment, with negative Wassermann and the patient in good general health, causes the physician to advise his patient that his disease is arrested or cured and that with due care he can engage in a regular or active business life. Insurance experience shows that a negative Wassermann means no sign of active syphilis was found in the blood specimen examined and any number of negative Wassermans, in our opinion, prove that the patient has received and reacted to proper treatment, but any company that accepts such cases at regular rates will pay an undue number of early claims. Syphilis cases properly treated are insurable but not at regular rates.

Diabetes is a condition that causes the clinician and insurance office much trouble. A disease which caused 17,000 deaths in the United States, as this did in 1922, and which is reported as increasing, must have many victims in the incipient and active stages. Probably as much has been written about this disease as any other in the medical and lay press during the last year or two. The physician has here, by the various kinds of treatment, especially diet or starvation and now by the use of

letin (insulin) and the education of the public, one of the best conditions in which he can improve his patients' health, but experience proves that the vigil must be closely maintained. Insurance experience shows that once a diabetic always a diabetic, and our problem is to determine whether the applicant whose urine shows glucose or whose history shows a former glycosuria or a suspicious train of symptoms, is merely an individual of low sugar tolerance, a pre or potential diabetic, or an actual active case. Methods of urinalysis and other means of examination are becoming so perfected that efficient protection is being offered insurance companies and the true diabetic is rarely considered an insurable risk at standard rates.

Urinalysis is one of the laboratory methods in which medical students have been quite thoroughly drilled and if, as in many instances, this instruction has been followed by a hospital internship the training has been such that physicians should make dependable qualitative examinations of urine specimens as they are secured from patients or from life insurance cases.

Why is it that so many insurance specimens, when checked in a local or Home Office laboratory, give different specific gravities or albumin or sugar reactions than those reported by the field examiners? Various theories have been advanced and I suppose mine is as good as another's. I believe the average practitioner is able to make a reliable qualitative urinalysis, but I know many of them do not as insurance examiners, and I think haste or carelessness is the reason for this. Fifteen years close association with Professor Walter S. Haines, one of the best teachers of medical students this country ever had, gave me an insight into methods of instruction in our better medical schools. Experience the last fifteen years with practitioners as insurance examiners and for over thirty years with clinicians has shown how rapidly the average physician falls away from the laboratory methods and technique he was taught in school. Many of his simpler cases he carries along without any laboratory tests and with the others he has become quite dependent upon hospitals, laboratories or public health departments.

Many of the insurance companies have established a central or Home Office laboratory for the examination of specimens of urine from their questionable cases. Thus they have a uniform method or standard by which these cases are judged and

all are treated alike. Our own laboratory so handled 40,000 specimens in 1923, not because we doubted the ability of our examiners but in order that we might take advantage of one standard instead of several thousand, as would have been the case had these examinations been made by our field examiners.

The clinician will always be necessary in the healing of the sick and more and more in the prevention of sickness, but if he has received nothing else from life insurance medicine he has been taught the value of blood pressure and the methods of taking it. Life insurance has furnished the only large collection of blood pressure reports on healthy men; it has shown that blood pressure increases with age or with weight, and that weight increases with age, but that the most increase in blood pressure comes after the age of forty. The blood pressure is affected by methods of living, eating and the use of alcohol, for the average dropped during the restricted diet of the late war and began to rise again in 1920. The records show that both systolic and diastolic rise with age and weight, but the systolic rise is greater than the diastolic, hence the pulse pressure also rises. Systolic readings above 140 mm. or diastolic above 100 mm. or pulse pressures below 30 mm. or above 50 mm. should be considered as danger signals in life insurance. Insurance records are reliable for people in average good health and they are taken with the applicants in a sitting position, usually during the course of their regular daily routine of living.

Addis (Arch. Int. Med. 1922) claims there is a striking difference in blood pressure taken before rising in the morning and after the individual has been up and around or later in the day and that the normal average of daytime measurements cannot be taken as a standard for patients who are standing or sitting up or exercising.

The insurance averages are made from records taken during the time the people are under the strain that tells and, therefore, they are the fairest to use as a basis for prognosis. Food, exercise and excitement all affect blood pressure, but not enough to interfere with life insurance for a healthy risk. If the observation is too high and remains so after eliminating any nervousness over the examination it will rarely come down without treatment.

Mr. Arthur Hunter, Chief Actuary of the New York Life Insurance Company, at the 1923 meet-

ing of the Association of Life Insurance Presidents, stated that the higher the blood pressure above the average the greater the mortality above the normal, and that persons with a distinctly high pressure are prone to develop diseases of the heart, blood vessels and kidneys, the mortality from heart disease, apoplexy and Bright's disease being very high among them. He further concludes from his observations and calculations that "Blood pressure is the same throughout the world under like conditions." It is principally affected by the kind of diet and the quantity of food, simplicity of living and freedom from nervous or physical strains having a beneficial effect. He believes that a reduction in blood pressure of Americans in the United States would result in greater longevity, that a better adjusted diet, containing less animal food, would result in a lower blood pressure and in greater longevity with an equal ability to carry on their various occupations.

I know of nothing better to close this brief and all too incomplete discussion than to quote the words of one of the leading Medical Directors of this country, Dr. Brandreth Symonds, Chief Medical Director of the Mutual Life Insurance Company of New York, who concluded his paper on blood pressure at the Thirty-third Annual Meeting of the Association of Life Insurance Medical Directors in 1922, as follows:

"Probably life insurance and general medicine will never regard blood pressure in the same light. Life insurance sees only people who are healthy or at least think they are. Even the highest pressure of fat elderly people is below 140 mm. on the average, if they are acceptable for life insurance. This also means that practically as many are below 140 mm. as above and we have seen that of those above 140 mm. nearly all of them are below 150 mm.

"General medicine on the other hand sees those who feel that they are sick. If their illness is due to blood pressure, it is usually high, frequently as high as 200 mm. or more. General medicine knows that these high pressures will come down to 170 mm. or 180 mm. by appropriate treatment and many of them live for years. There are examples among our own associates. But medicine does not realize that a small increase in the number of deaths per year means a great difference to life insurance. At age 50 we only expect 14 to die in the following year out of 1,000 living and we call that 100 per cent mortality. If 28 die, our mortality jumps up to 200 per cent. At age 60, if the number of deaths among 1,000 living increases from 26.69 to 40.04 the mortality increases to 150 per cent. If a practitioner should see 1,000 patients with high blood pressure at age 60 and bet with himself that 974 would survive the year and only 960 did survive he would not feel downcast; in fact, he would probably point to the record with pride and boast of his ability in prognosis. But life insurance would have to tell him that his mortality was 150 per cent in that group and a medical director who never made a better guess than that would not keep his position for long. General medicine would look complacently at the living, but life insurance would ruefully regard the dead, for forty claims would have to be paid instead of the twenty-six expected."

TULAREMIA (?) IN NEW YORK STATE

The appearance of a number of diseased wild rabbits in a western county of the State has been brought to the attention of the Division of Laboratories and Research. It was thought that there might be an outbreak of tularemia among these animals and steps were immediately taken by a local laboratory in that vicinity to obtain information concerning the examination for *bacterium tularense*.

The disease has been studied intensively in Utah, where it became quite prevalent among the farmers, incapacitating those infected for two or three months, frequently at the harvest season. Recently workers of the Hygienic Laboratory in Washington reported the finding of cases of the disease in infected rabbits in California, Utah, Wyoming, Idaho, Colorado, southern Indiana and Ohio, Tennessee, North Carolina and Washington, D. C. So far as is now known, this disease is confined to the United States. In New York State no report of cases suspected of being tularemia has been found. More is being heard of this disease, however, from other parts of the country, and it is important to be on the alert to prevent its introduction and spread in this State—especially among jack-rabbits and squirrels. The etiological agent may be transmitted from these infected animals to man by handling and dissecting such animals or by the bite of an insect. Francis, who

has made an extensive study of the disease, reports that blood-sucking flies, stable flies, rabbit lice, mice lice, squirrel fleas and bedbugs can carry the *bacterium tularense* from animal to animal.

The clinical picture of seven cases of tularemia in Utah was summarized by Lake and Francis of the United States Public Health Service as follows:

"All seven had a sudden onset of illness with fever, closely following an insect bite, which became the site of suppuration and which was accompanied by a consequent unilateral suppurative lymphadenitis of the glands, which immediately drained the bitten area. The constitutional disturbance was severe, as indicated by febrile attacks which lasted from three to six weeks and which were followed by slow convalescence. *Bacterium tularense* was isolated from the suppurating lymph glands in five cases and from the blood in two. Serological tests were positive for complement fixation and agglutination, using antigens composed of cultures of *bacterium tularense*."

The extremely infectious nature of the disease has been demonstrated by the fact that six laboratory men who were closely connected with the investigation of tularemia contracted it. This led to the adoption of a regulation in the Hygienic Laboratory in Washington which prevents cultures of *bacterium tularense* being sent to any institution. —*New York Health News*, Vol. 1, No. 7.

MEDICAL EXAMINERS' RELATIONSHIP TO THE COMPANY AND ITS BEARING ON MEDICAL SELECTION*

F. L. GROSVENOR, M.D.

Medical Director of the Travelers Life
Insurance Company
Hartford, Conn.

The practitioner frequently is of the opinion that the physician who devotes his entire time to the medical work of a life insurance company occupies an isolated position so far as contact with fellow members of his profession and opportunity to orient himself with the progress in medicine is concerned. He ventures his opinion without an understanding of the medical director's true environment.

My work during the past twenty years has afforded me the utmost satisfaction in the opportunity which I have had both for personal association and correspondence with not only examiners representing my company during that period but the contact into which I have been brought in various ways with the pure clinician or advanced research worker in medicine. I accepted your Chairman's very kind invitation because of the opportunity which it will afford me to enter into intimate contact with the medical representatives of my company in this territory and the opportunity which it will afford me to meet the scientific practitioners of this locality in general rather than in the hope of being able to say anything to you which might be of very great interest.

Occasionally one receives the statement from an examiner with regard to a particular risk which gives the impression that the examiner considers himself the only factor in selection, and because he considers the impairment in question either of very great moment or of no importance—his opinion usually depending upon his personal experience with a varied number of cases—that the company in its action should depend absolutely on his expression of opinion. It should always depend in a very large and I may say major measure upon his opinion with regard to the insurability of an applicant, but there are certain other features which are to be taken into consideration in order to attain a proper balance in action.

The insurance business is based on the law of average. The exposure in the experience of any

company is vastly greater than can be that of any clinician and consequently must be the guide in evaluating any favorable or unfavorable features rather than the experience of an individual practice. Upon this in my opinion is based the very considerable difference between so-called life insurance medical viewpoint and the clinical viewpoint.

Hardly a day passes but I have occasion to wish that some examiner or attending physician who informs an applicant or the agent representing that applicant that he is of the opinion the applicant will attain his full life term notwithstanding some granted physical impairment, which throws the applicant into a class the experience of which I know will be decidedly unfavorable, could have had an opportunity to read and digest this statement of Dr. Symonds.

Nevertheless medical examiners are the keystone of the arch in selection by life insurance companies. Other factors of selection work either for or against the success of a company which in its final analysis means the protection of the savings and investment which the individual policyholder has intrusted to the company. Selection by the medical examiner in making accurate physical examinations, solicitation of accurate personal and family histories and the expression of opinion as to the viability of the risk as a whole operate always to the success of a company provided the examiner is competent and conscientious and surely no larger proportion of any group of men is so constituted than is the case in a group of physicians acting as examiners for well operated life insurance companies.

Selection against the company consists first upon the so-termed self-selection on the part of an applicant. Occasionally it is with definite evasion and definite intent to defraud. More frequently it occurs even subconsciously on the part of one who does not feel up to par, who assigns no reason for his untoward yet minor symptoms except that he perhaps attributes to increased age more importance in the change in his feeling of well-being than is its due, but just naturally feels that he had better get as much coverage as possible while the opportunity is still present. Selection on the part of the agent may operate either for us or against the interest of a company and its policyholders, depending upon whether an agent is loyal to the welfare of his company or on the other hand his interest in his present commission entirely overshadows not only his interest in the welfare of the company and

*Read at the Fourth Annual Clinic Week of the Ramsey County Medical Society, St. Paul, January, 1924.

of the policyholders which he has been instrumental in placing on its books but his future or permanent standing with the company as well.

While a home office has an additional aid to selection in its tabulated experience, the features previously referred to constitute selection so far as the field is concerned.

The field examiner is not concerned with how risks shall be classified or acted upon at the home office. He is depended upon to present a true picture of the applicant's physical condition as found upon careful examination and to obtain an exact record of the applicant's personal and family history. With this picture the home office is able to properly classify the risks presented to it. The field examiner is, consequently, not in a position to assure an applicant or the agent as to what will be the company's action on a given case.

In making examinations he is expected to display tact and ability to meet the applicant on his own ground, so to speak, so that he may be at ease. This is not solely for the purpose of being agreeable to the applicant but also because one when at ease is most apt to give a fair statement.

An apparent lack of frankness on the part of the applicant may lead to the necessity of an examiner availing himself of decidedly searching questions, put from various different angles, in order to develop the truth to which the company is entitled before acting.

An examiner is not only justified in going beyond the questions on the blank, but is expected to do so provided the course of the examination develops anything which arouses his suspicion, and such action is not criticisable.

Examinations conducted in a too routine manner are not looked upon with favor. Short of drawing on the imagination, which I am satisfied good examiners never do, an examiner cannot be justly criticised for thoroughness in the matter of examinations.

So-called borderline cases receive favorable consideration at the hands of the home office medical officers when examined most thoroughly and conscientiously and to an extent which would not be possible if we accepted superficial examinations.

Examiners are selected and employed on the basis of their professional qualifications. Their adaptability is important but secondary. A competent diagnostician even though he be a crank in his relations with men is preferable to a weakling

in medicine even though the latter be as full of sunshine as a day in June. A combination of competency and sunshine is of course much to be desired when obtainable and that agent so situated that he has an opportunity of working with such a counsel of perfection is indeed fortunate. Perfection, however, is difficult of attainment.

Although the field examiner cannot render a decision as to the proper class in which an applicant should be placed, the home office action in this respect is based, so far as the medical aspect is concerned, upon the findings of the examiner so that one is entirely correct in stating that he is the most important factor in home office selection and the most important single contributing factor towards a satisfactory mortality upon which the success of a company and the protection of its policyholders depend.

It depends upon the home office medical department to maintain in the field its medical organization at the highest possible standard, appointing only examiners who are competent diagnosticians, painstaking and accurate and who will render true and accurate reports without fear or favor. Such a corps of field examiners can be maintained only in case its members can believe that they will be supported by the home office and its field representatives when they render good medical service in its most essential element, that is, assistance in medical selection.

The very necessary sense of loyalty to the company cannot be felt by its examiners unless they are able to feel that they have the support of the company when they conscientiously perform their duties in connection with medical selection.

If an examiner feels that officers responsible for the appointment and continuance of examiners attach undue weight to complaints made against them which are not true in fact but which consist of an enlargement of trivial matters made because a solicitor has taken exception to the company's action and holds the examiner responsible when he is only responsible in so far as he has done his duty in reporting the facts as determined, that examiner will lose his sense of loyalty and either decline to serve the company further as inconsistent with his ideals if he is a man of honor, or, if his ideals are not high, become less thorough and competent—either of which results is deplorable.

An examiner whose vision is broad can be of assistance to the selling force in many ways with-

out lessening in any way his value in the field in which he is essential, that of selection. However, he must never let his desire to accommodate interfere in any degree whatever with the really vital service for which he is employed, that of making competent examinations.

An examiner should never have cause to believe that continuance of his services is dependent upon any other than loyal and intelligent service.

We are all human, even we doctors, but I sometimes think that we should be more human than others because of our opportunity to observe the frailties of human nature and consequently should be less inclined to take exception to any unfairness. Still it is the natural inclination of the human mind to react to unjustified accusations by an indifference to the rights of the accusers.

I am satisfied that the agent who meets an examiner half way in the matter of the many accommodations which may enter into their relations aside from the matter of pure medical selection attains a much greater success in the handling of his business and enjoys his life of freedom from friction to a much greater extent than does the agent who looks upon an examiner as a necessary evil whose functions are to be considered on a low plane and to be overridden when possible. Suspicion breeds suspicion. Examiners and agents succeed in their relations when they meet on the ground of gentleman to gentleman.

Medical selection in so far as it refers to the physical condition of the applicant at the time of examination affects the mortality results for a period of perhaps five to six years from the date of issue, as by the end of that time a group of selected lives will have reached about the same physical condition as a group of applicants. Medical selection may influence the mortality to a certain extent for a greater period by giving due consideration to family and personal history as these are matters of history already sustained and with a consequently fixed value instead of being matters of possible future development as are physical impairments which may be found upon examination.

The work of the medical department begins with the examination of the applicant by the examiner in the field, which constitutes the first consideration of the insurability of the applicant by the company after solicitation on the part of the agent. The field examiner is depended upon to examine the applicant thoroughly, to report to the home

office a correct picture of his physical condition and to obtain complete and accurate information as to personal and family history. The examiner must be a competent physician gifted with the power of keen observation and must be trusted to observe any material conditions as regards surroundings, the results of improper habits and any factors which may bear upon the insurability of the applicant.

In many companies, including my own, the medical examiner's report of examination is forwarded to the home office direct by the examiner without passing through the hands of any agency representative. This plan is followed for the reason that the physical condition and personal history of an individual is a confidential matter, that knowing this he is more willing to enter into detail with the examiner with regard to personal and family history and that the examiner may not be subjected to criticism or pressure on the part of the interested agent because of findings obtained by the examiner since the agent is not made aware of the findings. Better work is consequently done by the examiners, and examiners have a very deep appreciation of the correct attitude of a company which deals with the matter in this way. This plan also lessens materially the amount of correspondence between the agent and the home office as regards the reason for the company's action in a given case.

An important feature in examiners' relationship to a company is its selection of examiners who shall represent the company in their communities, make satisfactory examinations, be both businesslike and professional in their relations with agents and applicants and at the same time always remember that their duty to the company requires that they report all material information to the company. In order to secure loyalty to the company and interested services on the part of examiners it is always necessary to sift to the bottom all field complaints regarding examiners so as to determine whether or not they are justified by the facts or dependent upon personal feeling upon the part of agents or applicants because of a necessary unfavorable action taken by the company on business previously submitted or because of personal dislike or differences between the examiner and the agent over matters not related to the business of the company. Examiners and agents are both apt to be men of strong character and as such frequently differ.

It may seem that one goes beyond the title of

this paper in mentioning the subject of the medical director but upon him depends so largely satisfactory or unsatisfactory relationship of the examiner with his company that I trust you will bear with me when I express some of my views of his necessary qualifications. He is brought into the problems of the field representatives and solicitors through correspondence and personal contact and must be able to instill a belief in his professional ability and fair-mindedness when called upon to settle questions which arise in connection with the efforts of solicitors. He must not permit himself to become unduly suspicious and antagonistic and it is frequently necessary for him to weigh the determined facts until he can obtain a true idea of the facts in connection with any complaint which may be made to him by the company's agents with regard to examiners or by examiners with regard to agents, yet this should always be undertaken with the intent to do justice to those concerned and not in the hope of fixing the blame on anyone in particular. This is very necessary in order that examiners in the field and agents as well shall have complete confidence in the medical department. Personal contact between examiners in the field and the medical director and his assistants by means of visits to the field and visits to the home office by examiners located at important points serve to co-ordinate the work of the home office medical department and its examiners in the field to greater degree than can be accomplished by other methods.

Occasionally complaints with regard to examiners are made by agents shortsighted as to their real interest to the effect that competent examiners are incompetent because of agency reasons. It may happen that an examiner very competent medically may be decidedly criticisable from a business point of view. Before such an instance can be admitted, however, the medical director must be assured that such is in fact the case and that the examiner is negligent of the company's interests and not the victim of allegations resultant upon his having given satisfactory medical service. The loyalty of examiners to the home office which is essential cannot be maintained unless unjust criticism of them will not be recognized. A mutual and entire confidence between the home office medical department and the field examiners is an absolute essential.

It has been interesting to me, and I thought it might be to you, to note how much of the time at

its annual meetings the Association of Life Insurance Medical Directors has seen fit to give to the subject of medical examiners and matters relating thereto since its organization. In its first fourteen years five addresses were made on the important subject of the medical examiner out of a total of twenty-five subjects discussed and the character of the work of the medical examiner entered as a basis into the development of the facts brought out in the remaining twenty papers. The subject has frequently been carefully covered in recent years and only a year or two ago a highly scientific medical director with an actuarial turn of mind conceived the idea that there might be a relationship between the mortality of the risks accepted in his company year by year and the percentage of negative answers by the examiners as to recommendation in each given year. Or perhaps it might be better stated that an increase in proportion of the risks not recommended by the examiner but accepted after postponement or various other modifications materially increase the general mortality, and vice versa. The discussion of this paper grew to be largely actuarial for the reason that those of us without actuarial information could not well comprehend it in its entirety. There is no doubt, however, in my mind that the doctor's premise was logical. The amount of work undertaken by him and by others at various times serves to indicate the importance and value of the medical examiner in his relationship to his company.

The medical section of the American Life Convention has also devoted a very considerable portion of its time to the matter of the medical examiner and his work.

Life insurance has become one of the bulwarks of the nation, permitting millions to exist with the comforting knowledge of the protection afforded their dependents by their investment and savings in it, which savings are uniformly invested in the development of sound industries—thereby again serving as a public benefit. The attention of many an individual is first called to correctible conditions of ill health or physical impairment when he undergoes an examination for life insurance and his life thereby prolonged. Surely a physician who devotes a portion or all of his time to life insurance work is even more justified in considering that he renders an efficient public service which constitutes the ideal of our profession than were he to limit his activities solely to the care of the ill or to preventive medicine.

PLEURISY IN RELATION TO LIFE INSURANCE*

ROBERT LEE ROWLEY, M.D.

Medical Director, Phoenix Mutual Life
Insurance Company

Hartford, Conn.

My purpose in presenting this subject is to emphasize facts which you already know in regard to the significance of pleurisy, but which some of you may not always have in mind when cases with such a history appear before you as applicants for life insurance.

A thought that is uppermost in the minds of insurance companies is whether or not a history of pleurisy means a history of a tuberculous infection.

The pleural cavities are readily accessible to bacterial invasion of all sorts and while the pleura may be involved as a result of extension of infection from the lungs, it would appear that infections more frequently occur through the lymphatic drainage from the head and neck.

Pleurisies that result from infection introduced through injuries through the chest wall, or as a result of a pneumonia that happens to be located on the surface of the lung, have a different bacteriological basis from those that occur unassociated with chest injuries and pneumonias, the so-called idiopathic pleurisies. It is this type of pleurisy that is so often due to tuberculous infection and that we have come to regard as a sign of tuberculosis and for that reason great care must be exercised in the selection of lives for insurance with such a history.

The reports from the Bureau of the Census at Washington tell us of the decrease in the tuberculosis death rate throughout the registration area of the United States during the past twenty years, amounting to about 50 per cent. with an especial decrease during the past five years. That this splendid result is in large measure due to increased hospital and sanatorium facilities for the care of the tuberculous was shown clearly by Dr. Louis I. Dublin in an address before the National Tuberculosis Association, June, 1923.

According to the last report we still have, however, in round numbers, about 100,000 deaths per year from tuberculosis.

From a general economic standpoint, this disease

has always been of prime importance through the fact that young adult lives have been so largely numbered among its victims. To the life insurance companies it has always been a heavy financial burden, notwithstanding the care exercised in the selection of lives.

It requires but a hasty scanning of medical literature of the past twenty-five years or more to be convinced that we are faced with the necessity of thinking of tuberculosis whenever we think of pleurisy.

In 1905, Von Ruck, of Asheville, in writing on this subject in the *New York Medical Journal* reviewed the literature up to that time and reported statistical studies of various workers in the field of tuberculosis, from which it was concluded that an overwhelming majority of cases of so-called idiopathic pleurisy were of tuberculous origin. "Not only was this relationship conclusively shown by exact scientific diagnosis, but it stands in harmony with clinical observations in many instances in which the development of tuberculous disease has followed attacks of primary pleurisy after varying periods of time."

Von Ruck then gave the tabulated results of a later group of observers which combined numbered about 750 cases, and about 55 per cent of these afterward became definitely tuberculous.

In the examination of history records of 1,000 cases of tuberculosis, Von Ruck found a history of pleurisy in only 22 per cent. He felt that this proportion was too small for he had not infrequently demonstrated physical signs clearly indicating pleural thickening in patients who had denied any history suggestive of pleurisy.

The intimate relationship between pleurisy and tuberculosis has been shown by still another line of investigation, and I know of no more scientific and conservative report of this work than appears in the "*American Review of Tuberculosis*," 1921, by Van Zwaluwenburg and Grabfield, of the Department of Roentgenology, University Hospital, University of Michigan. Three hundred and sixty-six consecutive chest examinations formed the basis of this study, which was dependent upon the interpretation of shadows found over the apices and with greater frequency over the right apex. The results were carefully charted to indicate involvement of pleura alone, pulmonary, or a combination of the two. After discarding certain cases, the final group included only those in which three

*Read at Fourth Annual Clinic Week, Ramsey County Medical Society, St. Paul, January, 1924.

observers working together agreed as to the condition present.

While these cases were presented for examination in the three summer months when respiratory infections could be expected to be the least prevalent, some pathology of lung or pleura was found in about 50 per cent. The findings in the order of their frequency were: right apical pleuritis; left apical pleuritis; right pulmonary apical and left pulmonary apical involvement. By insensible gradations the shadows of pleural involvement pass into those of frank pulmonary involvement, and there is thus afforded another demonstration of the close association of apical pleuritis with pulmonary tuberculosis.

This work further points to the fact that chronologically the apical pleuritis precedes the pulmonary involvement. The infection probably reaches the pleura through the cervical lymphatic system and the prevailing tendency to spread is first to the opposite apex and then to the underlying lung tissue.

Turning now to the contribution to this subject that has been given by the life insurance companies, we find abundant testimony as to the soundness of the view that idiopathic pleurisy is, in the majority of instances, a tuberculous disease.

All of you perhaps know that a few years ago data were furnished by practically all of the large companies for a gigantic statistical study which was conducted by a committee composed of actuaries and medical directors. Among the subjects included in this investigation was the influence of a history of pleurisy on mortality of insured lives. The data contributed by the companies were based upon male lives accepted for insurance at standard rates covering a period of twenty-four years.

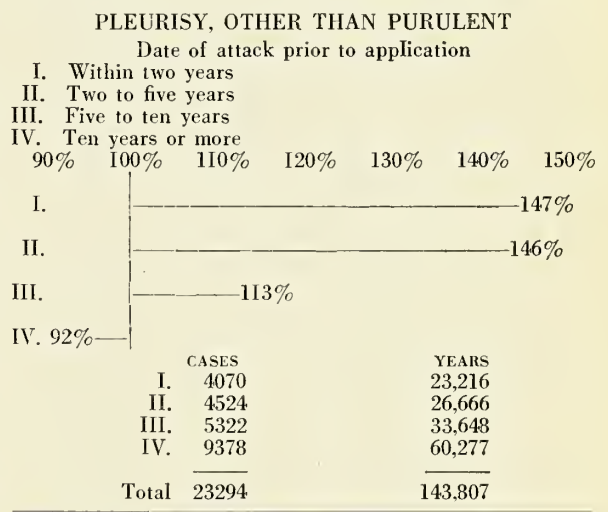

While the issues of only one month (January of odd years and July of even years) of each year was included, the abundance of data is indicated by the fact that over 23,000 lives were studied.

It is to be remembered that this was not a general population group, but a group of lives accepted for insurance after a medical examination and a review at the home office of all contributing information in support of or against the belief as to the presence of a tuberculous condition.

Mortality tables showing the expected death rate at each age among standard insured lives and covering the same period, were constructed and with those tables as a standard of comparison it was

found that lives insured with a history of pleurisy (non-purulent) within five years of date of application gave a mortality experience about 50 per cent greater than the normal or standard, which means that in a group of lives in which the normal expectation was 100 deaths per year there actually were 150 deaths.

The statistical material was divided into groups according to the period of time between the history of pleurisy and the acceptance of the lives for insurance. On this basis four groups were made on those accepted, (1) within the first two years, (2) between two and five years, (3) between five and ten years, (4) after ten years.

The above chart shows graphically that for insurance with the history of pleurisy, not more than five years removed, gave mortalities which were quite unsatisfactory. In reading the chart, the vertical line at the left may be regarded as indicating normal or standard (100%) mortality, and the departures from normal mortality by the lateral lines.

Figures are available to indicate the expected number of deaths in any group from each of the common causes, and applying that knowledge here, we find that the increased mortality is, in large measure, due to tuberculosis, for the number of deaths from that cause was three times the normal.

Furthermore, conforming to our general knowledge of tuberculosis, the mortality was relatively greater in the younger lives and also in those of under average weight.

This immensely valuable statistical study gives us reasonably firm ground on which to stand in our conclusions that the so-called idiopathic pleu-

risies are, in most instances, a manifestation of a tuberculous infection.

It is believed that the pleura acts to some degree as a barrier against the further spread of infection, but its effectiveness in this rôle is to be determined in individual cases only after a lapse of time sufficient to warrant the assumption of an arrest of the disease.

Those of us whose work does not bring us in intimate and frequent contact with tuberculosis need to be reminded from time to time of truths which we have long known, and it is with this thought in mind that I have been led to bring this subject to your attention.

The discovery and development of Insulin by Dr. F. G. Banting, Mr. C. H. Best and other co-operating investigators has brought relief to a multitude of sufferers from diabetes throughout the world. At a low price this boon has been placed within reach of all. But it is well known that only a beginning has been made in alleviation even of this one malady. Notwithstanding the magnificent advances that have been effected in arresting or averting many of the most grievous attacks of disease on human life, mankind is beset by enemies. Their strategy must be discovered and circumvented. This can be done only by patient research conducted in the main by skilled investigators who devote their lives to scientific inquiry. For these investigators the public at large must provide the means of support, for they it is who benefit immensely thereby. Such work has been going on quietly all over the world. Laboratories in the universities have groups of investigators working in co-operation under the direction of competent scientists. But only now and then does a result such as Dr. Banting achieved strike the imagination of the world. It is therefore but appropriate that advantage should be taken of it to appeal to the grateful public for support in making possible the continuance and prosecution of this work and of other investigations in medical science. To effect this and to signalize the discovery and the development of Insulin, the Banting Research Foundation has been created.

The purposes of this Foundation have been defined to be:

(a) To provide, in the first instance, further funds for the support of the Banting and Best Chair of Medical Research at the University of Toronto.

(b) To establish a fund for the adequate financial support of such scientific workers as may have proposed definite problems of medical research, and for whom funds are not otherwise available. Such assistance may be given to persons working in the University of Toronto or elsewhere.

All financial arrangements in connection with the collection and reception of the principal and subsequent expenditure of the income of the fund have been vested in a Board of Trustees, the members of which are appointed for a term of three years subject to reappointment at the end of their respective terms of office. The Trustees propose to make an appeal to the public for funds in the immediate future.

F. LORNE HUTCHISON,
Honorary Secretary.

THE VALUE OF MEDICAL EXAMINATIONS IN LIFE INSURANCE*

D. E. W. WENSTRAND, M.D.

Assistant Medical Director of the Northwestern
Mutual Life Insurance Company

Milwaukee

On first thought, a subject such as mine may seem too elementary and almost unworthy of discussion, for, of course, most any one will say that there can be no question of the value of and the need for a medical examination before insurance can be issued to an applicant. However, I have in mind not only this value, but also the relative or the comparative value of one examination, or type of examination, as against another group or type. We who are reviewing thousands of examinations a month, from thousands of examiners, form rather definite ideas as to the kind of examination which is most valuable to us, and it is with the hope of transmitting some of these conclusions to you that this title has been chosen.

Moreover, there is a tendency, I believe, among certain life insurance executives, to question the value and the need of medical examinations in risk selection. Witness, for example, the practice of some Canadian companies who issue policies up to a certain amount without examination, also group insurance and industrial insurance. It is not very difficult to understand why an executive should have this doubt when he sees claims being paid every day on those who have been insured only a few months or a year or two, and finds such causes of death as cancer, tuberculosis, paresis, apoplexy, organic heart disease, nephritis, etc. A presumably careful examination was made only a short time before by a supposedly well qualified doctor, who reported nothing abnormal either in the history or physically. Even the medical director sometimes wonders if a careful examination was made. Very naturally both may well ask why American life insurance companies paid almost 15 million dollars to their examiners in 1922, and a great deal more last year. Of course, we know that physical signs are often obscure or even absent, that it would take a Philadelphia lawyer to question and cross question some applicants in order to get the facts, and that diagnosis, at best, is subject to many human errors. However, I am convinced that it is up to

*Read at Fourth Annual Clinic Week, Ramsey County Medical Society, St. Paul, January, 1924.

us of the medical profession to demonstrate, as we never have before, that medical examinations in life insurance are valuable and necessary in order to obtain a satisfactory mortality, and to justify the annual expenditure of millions of dollars for these examinations by giving as intelligent and painstaking service to life insurance companies as we do to our patients. The service rendered in securing protection against death to the deserving thousands, yes millions, who receive insurance each year at a low cost and with safety, is as commendable and praiseworthy as the service given to suffering individuals whom we see on our daily rounds. Think what eleven and a half billion dollars of insurance, issued last year, will mean to widows and orphans of the years to come! Careful examinations and intelligent medical selection are the fundamental safeguards of the insuring public, without which the most inspired financial management would be useless. The savings from the mortality factor, together with the interest earnings and a low expense ratio, represent the difference between the gross tabular premium and the net cost of the insurance. The company and the department, which I represent, feel very strongly this responsibility to give our policyholders protection at the lowest cost which is consistent with good business principles, consequently we must exclude poor risks. I am sure that the same applies to all conservative and well conducted companies. It shall be my purpose, therefore, to try to show briefly how this is done and at the same time to plead for the conscientious co-operation of the local examiners to help in this laudable effort.

Our premise, then, is this: that the determination of an applicant's insurability depends primarily upon the medical examination. In the early days of life insurance, the applicant was not examined. He simply furnished certificates of birth, of good health and of good character. With the advent of active solicitation, as the agency system grew, and with a consequent increase of the chances of selection against the company, medical examinations became more necessary and, as time went on, more exacting, to protect against impaired lives. It is a well known fact, yes, almost axiomatic, that the impaired life seeks insurance, while the healthy and normal individual must be urged to apply. The marked advance in physical diagnosis, following the middle of last century, was another factor which stimulated insurance examinations, and since

then the bond between the two has become closer and closer.

It was not until the seventies that medical selection began to build on a safer foundation by cementing an alliance with the actuarial science. Before that time, the selection of risks depended almost entirely upon the individual judgment and experience of the doctor who did the selecting, and the law of averages was scarcely considered. As the years went by, medical directors and actuaries began to work together and to formulate rules for risk selection. Some of the earliest studies in this new medico-actuarial science were undertaken by the famous actuary, Emory McClintock, when he made an investigation, in 1877, of the Northwestern's mortality experience by special groups of risks. The first count covered such classes as residence, occupations, amounts, kinds of policies, male and female risks, etc. In '79, the first truly physical impairment was investigated, namely, overweight. In the late '80's, a few classes, including family and personal histories, were suggested by Doctor Fisher as worthy of actuarial investigation. From these beginnings grew, through many intermediate steps, the later combined studies of the thirty-four companies in 1903, and the forty-three companies in 1912. In this last mortality investigation, 183 classes or groups were investigated, including occupations, medical impairments, habits, family history, build, habitat, races, etc. This is now the principal basis for risk selection, except as individual companies have counts of their own which are sufficiently large to be followed safely. Now all this statistical material, to be valuable and accurate, presupposes careful medical examinations from which the data have been gathered. The results obtained from the use of these tables in risk selection seem to indicate that the examinations were made with reasonable care. However, another factor contributed to the accuracy of the figures obtained, namely, numbers. Approximately three million policies were studied, and of course the relatively small percentage of poor examinations was probably not sufficiently great to disturb the general averages. However, if this information is valuable as it stands, how much more so would it not be, had every examination been made with proper appreciation of the need of accurate information?

This is not the time nor the place to give an exposition of risk selection as it is worked out in de-

tail, for this cannot be handled briefly, but I do wish to repeat and to emphasize the statement, again and again, that a careful examination is the primary requisite to the proper valuation of a risk.

We who, at the home office, review the reports of the examiners in the field, must have confidence in the pictures of the applicants which are sent to us. You are our eyes, ears and hands, which convey accurate impressions of the man before you, so that we may be able to place him in this or that group and decide as to his insurability. An examiner represents directly the medical department by which he was appointed and he must ever have its interest in mind rather than that of the agent or of the applicant. First and last it is the examiner's duty to report the facts as he finds them. He is being paid for furnishing a word picture of the applicant and not for his opinion as to the man's insurability. Please do not misunderstand me. We do appreciate your opinion of the interpretation of symptoms, conditions and physical findings, but the medical director is especially trained to evaluate these with respect to risk selection as determined by the law of averages. He does not think in terms of individuals but in terms of large groups under observation for a long term of years.

A life insurance medical examination blank is simply a somewhat extended history sheet, where specific questions are asked in regard to an individual's age, race, social status, residence, insurance history, occupation, weight, habits, family history and personal history. Also the blank contains a number of questions as to the physical condition as brought out by the examination of the circulatory, the respiratory, the digestive, the genito-urinary and the nervous systems. Perhaps the day will come when the blank of many questions may be discarded, and it will be possible to depend upon the informal report of the examiner, relying upon him to bring out all the salient points. But not yet have we reached this state, though each company no doubt has many examiners who could be allowed this freedom. However, it is well to remember that as a chain is only as strong as its weakest link, so an examination blank must be made to fit the weakest examiner.

From an observation of many years, I am impressed with the perfunctory way in which many examinations are made. It is apparent that we have not entirely gotten away from the early idea in life insurance that every man who applies for a

policy should get it, for his dependents need the protection. On the other hand, the primary consideration in an examination is to safeguard the interests of those who are already policyholders. To become a policyholder, the applicant must measure up to a certain standard, which differs somewhat in various companies, but the examiner has only one duty to perform and that is to give the facts in the case as they are brought out by the questions on the blank. No matter how well the doctor knows the applicant, the questions must be asked and the examination made, taking nothing for granted. Many instances could be cited where an examiner has been much embarrassed because he failed to draw out a complete history from a well known applicant. Only the other day we received an examination which gave no history of any digestive disturbance and showed nothing abnormal. Almost in the same mail came a letter from the examiner which told us that the man had been operated on for gastric ulcer two days after the examination was made. Of course the applicant withheld facts in regard to his history, but it is well to have in mind always that this is not uncommon, and that a little time and patience in asking the questions might bear fruit. Your patient comes to you and, as a rule, tells you freely and fully all his symptoms, but the applicant for insurance expects you to find out about his past symptoms and diseases by definite questions. Oftentimes the acute examiner, by minor leads, unearths important facts. Don't overlook the importance of the history. There are many diseases which constitute distinct impairments and cause either limitation or rejection. Some companies reject applicants who have had gallstones, gastric or duodenal ulcer, epilepsy, syphilis, epithelioma, tuberculosis, etc. Certain other conditions are sufficient reason to postpone for a definite period; for example, appendicitis, renal colic, pleurisy, articular rheumatism, malaria, nervous prostration, asthma, sunstroke, etc. The practices of the different companies need not worry the examiner; he will learn them in time; but it is necessary that he question the applicant sufficiently to form an opinion as to the nature of the disease, and, if there is still a doubt in his mind, to secure the diagnosis from the attending physician. In this connection, an examiner should decide in his own mind what is important and what is unimportant, but surely he should recognize the fact that if a condition is worthy of mention it is also worthy of explanation.

Much of our correspondence is caused by unexplained and incomplete or omitted answers. As a matter of general information, it is well to mention that that part of the examination which is signed by the applicant becomes a part of his contract and must be complete in every detail; further, that corrections and additions to this part, after the paper has been signed, must be attested by the applicant and not by the examiner.

In the history appear also questions as to occupation and habits. These are not primarily medical in nature, but they are just as pertinent. Many occupations are hazardous and cause rejection or limitation. Perhaps there is no one phase of medical selection which causes so much confusion as occupations, for one company accepts what another declines, and some companies rate up certain occupations which are accepted freely by others at standard rates. This will all be ironed out in time and standardized, but in the meantime the examiner can help by putting down a careful statement as to the nature of any unusual trade or occupation.

Habits in the use of alcoholics are most important. There are no questions on the blank which cause more trouble, for men are most reluctant to give the facts, especially now since we have so-called prohibition. An examiner should never assume that he knows all about a man's habits and try to answer these questions without asking them. Nor should he allow an applicant to record answers which are not in accordance with the facts as they are known to the examiner. There have been many studies of the effect of the use of alcoholics on mortality and it has been demonstrated repeatedly that total abstainers are the best risks, while the mortality rate increases in proportion to the amount of alcohol used. (Table I.) Therefore the value of the examination depends also upon the ingenuity of the examiner in eliciting the correct answers to these questions.

A proper physical examination can not be made hurriedly nor in noisy surroundings. It must be made with the same painstaking effort that you give your patient when he comes to consult you for an obscure condition. As with the history, a certain number of applicants have something to hide and they will not help you to discover the impairment. Many a man has a history of a previous rejection which he does not admit. Of course the company will know about it through the "Interchange" and I know, from experience, that it is rather embar-

rassing to be informed that a goiter or a heart murmur, or albumin, or sugar has been found more or less recently in an applicant, who was passed as first class in every way, and then discover, upon re-examination, that the impairment is still present.

Summary of the Mortality Experience of The Northwestern Mutual Life Insurance Company, with reference to use of Intoxicants. AM Select and Ultimate Table.

	Policies	Deaths	Actual	Tabular	Percent
A- Total Abstainers	132,649	4,967	10,960,600	15,745,739	69.6
B- Moderate Users	110,136	5,224	18,045,300	23,252,821	77.6
C- Regular Beer Drinkers	15,412	767	2,247,200	2,464,707	91.2
D- Regular Spirit Drinkers	3,206	289	1,601,100	1,257,773	127.3
All Classes	261,403	11,247	32,854,200	42,721,040	76.9

(Issues 1901-1908 inclusive to Anniversary in 1915.)

TABLE I

In explanation of above table, the following rules were used to govern classification:

A. Total Abstainers.

B. Moderate Users of either Malt, Vinous or Spirituous Beverages.

1. Beer or ale, not daily nor more than 3 in any one day at the most.
2. Porter or strong ale, not daily nor more than 2 in any one day at the most.
3. Light wine, not daily nor more than 4 in any one day at most.
4. Strong wine, not daily nor more than 3 in any one day at most.
5. Spirituous liquor, not daily, nor more than 2 in any one day at most.

C. Regular Beer Drinkers

1. One who uses four or more glasses of beer or ale in any one day at most, or 5 or more in a week, or a daily practice of 1 or more. Include where wine or whisky is also used moderately but not enough for Class "D."
2. No "wine only" cases in this class.
3. Two glasses of beer and wine a day.
4. Beer and wine at meals, moderately.
5. Porter or strong ale daily, or 3 or more in any one day at most.

D. Regular Spirit Drinkers

1. One who uses all kinds but not entitled to Class "B."
2. Wine daily, 5 light, 4 strong, or more.
3. Spirituous liquors daily, one or two drinks a day, or 3 or more in any one day at most.
4. Two glasses of beer or wine or whisky a day.

The Company has never knowingly accepted men who might be termed free users of either beer, wine or whisky, nor those who use alcohol to the extent of intoxication at times.

It was missed only through carelessness, but that is no excuse. An examiner must be ever on guard against the dishonest applicant. Fortunately there are not many such, but still it is strange how a man may justify himself in putting something over on an insurance company when in all other business deals he may be most scrupulous. Again the idea is prevalent that it is up to the doctor and to the company to find out, and, if he can get by, he holds himself blameless. Has an applicant been coached or specially prepared for the examination? It is well to think of this possibility. For example, is it not possible for a diabetic to pass a satisfactory examination, if he withholds the history and is under treatment with insulin or on a modified diet? The careful examiner would undoubtedly note the marks of the hypodermic needle or have his attention called to the subterfuge in some other way. Let me cite an example of a rather remarkable instance of careful observation. Two or three months ago, one of our examiners reported upon a man that he could not find anything definitely wrong with the circulatory system, but still there was a doubt in his mind as to the condition of the myocardium. He asked that we get the opinion of another doctor. The second examiner also reported that the heart sounds were normal, except for some disturbance of rate and rhythm; the blood pressure was normal, and so was the urine. We declined the risk. A few days ago we were informed that this man died suddenly. This is the kind of opinion and co-operation which is valuable.

No paper by one of Doctor Fisher's assistants would be complete without some words about blood pressure. We all know of many men and women who have lived for years with a high blood pressure, but we have demonstrated that on the average, large groups of men with a persistently high arterial tension show a mortality higher than normal. (Table II.)

Perhaps I have said some things which might be construed as a criticism of our profession. If such it is, I hope that it may be thought constructive and of some value. I believe in the medical profession, and I further believe that there is no other profession or class of men which, as a whole, ranks higher in honor and integrity or in the service given. In the early history of life insurance, many companies would not permit a family physician, even though he were an appointed examiner, to examine his pa-

TABLE II.

Summary of the Mortality Experience of The Northwestern Mutual Life Insurance Company, with respect to the Palpatory Systolic and Auscultatory Diastolic Blood Pressure									
Year of Entry	Average Systolic Pressure	Average Diastolic Pressure	Number of Cases Accepted	Number of Cases Rejected	Average Age at Death	Ratio Annual to Expected Mortality (Cannons No. 7 table)			
						100 %	150 %	200 %	%
1913-1920	Low Blood Pressure (90 mm. and under)	10.00	3380	28	35				100.0
1921-1922	Dependent Blood Pressure (90 mm. and under)	10.00	1347	71	33				79.0
1923-1924	Dependent Blood Pressure (90 mm. and under)	10.00	40-60	2070	310				84.0
1925-1926	Dependent Blood Pressure (90 mm. and under)	10.00	40-60	230	90				114.0
Risk Rejected for High Blood Pressure Only from 1927-1928-Mortality Compared to Cannons No. 7 table	Low Blood Pressure (90 mm. and under)	10.00	743	19	35				100.0
	Dependent Blood Pressure (90 mm. and under)	10.00	711	34	33				120.0
	Dependent Blood Pressure (90 mm. and under)	10.00	1190	181	33				124.0
	Dependent Blood Pressure (90 mm. and under)	10.00	1465	274	33				150.0
	Total	10.00	4163	307	33				120.0
	High Blood Pressure (90 mm. and over)	10.00	325	35	35				100.0
	High Blood Pressure (90 mm. and over)	10.00	1085	125	33				120.0
	High Blood Pressure (90 mm. and over)	10.00	998	131	33				120.0
	High Blood Pressure (90 mm. and over)	10.00	627	121	33				120.0
	Total	10.00	309	134	33				120.0
*The Northwestern Mutual Life Insurance Company's General Mortality Experience about 80% of the Table									
†Expected Mortality									

TABLE II

Table II gives a summary of the Northwestern's Blood Pressure Studies. The palpatory systolic pressure has been used uniformly throughout because this was the way we began. The groups referred to in the first four lines are accepted risks. All the others are rejected risks. We were able to follow these latter cases,

- 1st, by previous policies in this company,
- 2d, by information from other companies,
- 3d, by correspondence with examiners and agents.

In this way we learned when death occurred and in most cases the causes of death.

No cases are included where the blood pressure later became normal.

In none of these cases was any other impairment found; the rejection was based wholly on hypertension.

Of the 507 deaths, 363 were due to cardio-vascular and renal diseases, or a little over 71 per cent.

It is apparent, from this study, that a persistently high systolic arterial tension results in an excessive mortality, and the higher the pressure the greater the death rate.

tient for life insurance, for fear of prejudice in favor of the patient. It seemed to Doctor Fisher that this reasoning was wrong, for the family physician, provided he was honest, was in a better position to furnish the company with reliable information concerning the applicant's past and present health record than any one else. So such examinations were encouraged. About thirty years ago, we began to keep a record of all approved examinations made by a regularly appointed examiner of the company, who was also the applicant's family physician. A few years ago, 38,550 such cases had been accumulated and the mortality of the class was 12 points better than the general average mortality of the company for the same period. "This certainly speaks well for the integrity of the man whose duty lies in one direction and his sympathies in another."

In conclusion:

1. A life insurance examination is a serious undertaking, upon which depend a satisfactory risk selection and a favorable mortality.

2. Its value to the company you serve rests upon the facts which you are able to elicit by careful history taking and through physical examination.

3. Let us all, both examiners and home office representatives, bear in mind that when a poor risk is given insurance and becomes an early claim, it is the policyholders who pay the loss, for they constitute the company. On the other hand, when we are diligent in our efforts to exclude such risks, we render a distinct service to the large numbers who depend upon us for the protection of their families at the lowest possible cost. Our consideration must always be the greatest good for the greatest number.

WOULD-BE SYLPHS MUST QUIT EXTRAS

Eating little at meal times and much in between is the poor system which most persons employ to cut down their weight. Then they wonder why the scales are discouraging to any honest effort to reduce.

Some pitfalls in the path of those who have joined "the cult of sylphs" are given by Dr. L. M. Davidoff, Boston physician, in a humorous but helpful article entitled "Now This Matter of Reducing Weight!" which is featured in the April issue of *HYGEIA*, popular health journal.

Tidbits and "extras" cause the downfall of most of those who are following the national craze for reducing, says the article.

The average woman needs a diet of between 2,300 and 2,800 calories per day; a healthy man's diet should consist of between 2,800 and 3,000 calories daily. To reduce weight appreciably it is necessary to cut down to 1,600 calories.

"But suppose," says Dr. Davidoff, "that a woman has reduced her food intake to 1,600 calories at meal times, let us consider what her extra tidbits amount to."

One pound of chocolates even though it is made to last over four days will be equal to about 800 calories a day.

Tea with sugar and without cream adds another 40 calories.

One cup cake with the tea raises the total by 150 calories.

Tasting the dinner, eating the extra frosting, "not wasting" the whipped cream, etc., adds 200 calories more.

Then it is a shame to throw away perfectly good food that is left over from meals! Think of the poor orphans across the water who haven't even bread enough! So instead of the garbage pail, 300 or 400 calories more.

The "apple a day" is eaten religiously with a resulting addition of 50 calories.

If it is theater night, or bridge night, or sewing circle night, two or three delicate cheese sandwiches with hot chocolate and whipped cream—500 calories.

FUNDAMENTAL PRINCIPLES AND RECENT CONCLUSIONS IN SURGERY OF CONGENITAL CLEFT PALATE*

TRUMAN W. BROPHY, M.D., D.D.S., F.A.C.S.
Chicago

While attending the Pennsylvania College of Dental Surgery of Philadelphia I also had the privilege of attending the surgical clinics of Dr. James E. Garretson, the father of oral surgery and the foremost man of his time in this special field of work. It was my further opportunity and pleasure to attend regularly the clinics of Dr. S. D. Gross, the father of American surgery, of Dr. Joseph Pancoast, one of the foremost surgeons of his time, of Dr. J. Ewing Mears and of Dr. D. Hayes Agnew, whose name was broadcast throughout the world by reason of his services to our martyred president, James A. Garfield.

After graduation fifty-one years ago I concluded that, inasmuch as I had never before been as far east as the boundary between Illinois and Indiana, I would visit the surgical clinics of Washington, Baltimore, New York and Boston, presuming that I would never again have an opportunity to travel so far east.

In New York I visited the clinics of various surgeons of renown, among whom was the leading orthopedic surgeon of the day, Dr. Louis Sayre. I presume many of you know that he was congenitally lame. Probably through his misfortune he was led into surgery, and orthopedics especially appealed to him.

It was in Dr. Sayre's clinic that I was prompted to undertake a kind of work which he declared was impossible. To this clinic, which was large, patients came who suffered from all sorts of deformities, congenital and acquired. On my first visit, there was among them a tall, thin, poorly clad woman, bearing all the evidences of extreme poverty. In coming, she had faced a snow and rain storm, so common in the last days of March. Her face wore an anxious, troubled look. She had brought her little child, two weeks old, to the great surgeon with the hope that it might be cured.

Its deformity was one of the most conspicuous and distressing that ever saddens a home. It consisted in protruding premaxillæ, double cleft lip

*Read by invitation before Minneapolis Surgical Society, Dec. 6, 1923.

and complete cleft of the palate, the vomer not being attached to either side.

The surgeon took the child in his hands and explained to the class the nature of the deformity. He said in substance, "Gentlemen: This child's deformity is so extensive, the tissues are so abnormally placed, that it is not amenable to successful treatment—the treatment that would bring all the parts into normal relation. You will observe that the premaxillary bones are more prominent than the nose: the prolabium is far removed from the lateral portions of the lip. We have one course open to us and that is to excise the bones, after which the clefts in the lip may be closed." He held the child up before the class and said, "I grasp with my hand the sides of the child's face and find that I am able to move the bones toward each other. If we had some way by which these bones might be approximated, the premaxillary bones brought into correct relation with the maxillæ and if we could, after placing them in contact, immobilize them and bring about a union, we could go far toward correcting the deformity. But such an operation has never been performed. We have no means of doing it."

The doctor handed the little child back to its weeping mother, who stood holding it fondly in her arms, still looking at him while he informed the class that some months later he would excise the premaxillæ and sew up the lip and when the child was nearly grown an artificial palate could be provided as an aid to speech.

The incident was tragic. The expression of the mother's face I can never forget. She turned away with a saddened heart, to wander through the beating storm with a feeling that there was scarcely any hope for her unfortunate child. A deep impression was made upon the class. Not a sound was heard among the students while the child's condition was being described by the surgeon. Everyone, it seemed to me, was in deep sympathy with the mother. Such was the experience of this mother—and even today oftentimes little hope of help is offered to the mother, who is always the greatest sufferer.

I repeat Professor Sayre's statement: "I grasp the sides of the child's face with my hand and find that I can move the maxillary bones toward each other. If we had some way by which these bones might be approximated, the premaxillary bones brought into correct contact with the maxillæ and

if we could, after placing the bones in contact, immobilize them and bring about a union, we could go far toward correcting the most conspicuous deformity known to mankind. But such an operation has never been performed. We have no way of doing it." The pale-faced, disappointed mother is still before me; the stentorian voice of the late premier American orthopedic surgeon still rings in my ears as he said: "Such an operation has never been performed. We have no way of doing it."

It was then I was obsessed with a desire which has been never-failing but increasing to devise a way that would enable me to bring about a union of the separated, misplaced bones in such deformities. More than the average human lifetime has been devoted to devising and improving a method which will give as a result a hard palate of normal breadth, a long, flexible, well-formed soft palate and an arch or framework upon which to construct a full, well-shaped lip and normal nose. Upon my return home in the spring of 1872, I began to work conducting experiments upon the bones of young animals. Professor Garretson had told us that because of the fact that the bone was not sufficiently ossified to fracture, he could take the tibia of a kitten and tie it in a knot. It is estimated that at birth, bone is about one-half organic matter and therefore capable of bending or moving when pressure is made upon it. So I believed that the maxillary bones in a young cleft palate patient might be bent and moved into proximity.

I found that at that time in New York City and quite generally through the country, many of the leading surgeons had abandoned palato-plastic surgery on the ground that their operations were generally failures. Garretson has said: "As generally practiced, it is rather difficult of performance and so frequently unsuccessful that the surgeons seem disposed to avoid the responsibility of it." Non-union occurred in a large majority of their operations and failure of function nearly always followed. Had they understood the proper age at which to perform these operations, the order of procedure of the different steps and especially the correct technic of the bone surgery essential to this work, they would have operated on these patients in infancy with good results.

From 1860 to 1880 and later, the great prosthetist, Norman W. Kingsley of New York, with numerous assistants, was occupied with construction

of artificial vela for cleft palate patients, many of whom had undergone unsuccessful operations.

In the light of surgical advancement and the development of modern methods of procedure, the old time theory that infants could not endure palate operations and that they should be made only on children from seven to ten years of age or thereabouts, has become a thing of the past. We now know that every advantage is gained by early operation which allows the proper order of procedure; less shock and reaction, greater ease of manipulation and results in correct function. To delay operating until after habits of speech have been developed, which are frequently so defective that the individual cannot be understood, is oftentimes an irreparable mistake.

All surgery of the palate should have for its goal perfect function, that is, perfect speech. The test of success is the quality of enunciation resulting. Two phases of palatal surgery have especially to do with this: first, the union of the separated bones of the palate including the management of the premaxillæ and, second, the control of the tuberosities in their relation to the soft palate. These two fundamentals I wish to emphasize, for without a proper conception and execution of these in palatal surgery there is small hope of securing satisfactory results either in form or function.

I wish to present to you briefly the course which I am convinced leads to the nearest approach to normal form and function in the palate. This course provides for operation in early infancy, it contemplates the establishment of a *normal palatal arch* and the *prevention* of the *spreading* of the *tuberosities*, it calls for *three stages* in the treatment of typical double cleft of the lip and palate and *sometimes four*, if complicated by protruding premaxillæ. These stages are as follows: (1) the freshening, approximation and immobilization of the cleft bones so that union may take place; (2) the closure of the lip; (3) the closure of the soft palate; (4) elevating the nose, which may have become flattened by moving the premaxillæ backward.

1. This step should be done as soon after birth as is expedient. I have found the fourth to tenth week most satisfactory, as in an otherwise normal child all functions of the body have become fairly well established by that time.

2. The closing of the lip should be done in

from six to ten weeks after the bones have been approximated.

3. The closing of the soft palate should be deferred until just before speech is attempted, that is, not earlier than the eighteenth month.

4. The nose should, if necessary, be elevated later.

While agreement is fairly general now as to the wisdom of the early operation, uniform procedure is not so general. It is still all too common to find surgeons closing the lip first, depending upon the traction of the orbicularis oris muscle to accomplish the desired effect upon the bones; or passing a single wire through the anterior part of the separated maxillæ, thus bringing them together. The closing of the lip and the resultant traction of the orbicularis oris muscle *will* gradually move the anterior part of the cleft bones into contact, but the bones will not, as a rule, be normally approximated or united. The bone carrying the premaxilla protrudes beyond the maxilla of the opposite side, leaving an ugly malformation of the nose and arch. Besides, there cannot be union of the bones with the muco-periosteum intervening. They may not even meet, they remain malposed and leave the patient deformed throughout life.

A wire suture passed through the anterior part of the cleft bones will often cut out. It is more than likely to do so unless an incision is made over the line of union between the maxilla and premaxilla of the side opposite the cleft, the anterior half of the bone separated, the protruding premaxilla crowded downward, either bending or fracturing the lingual surfaces of the bone, so that an approximation of the cleft in the alveolar processes may be made.

MANAGEMENT OF PREMAXILLAE (Fig. 1)

A review of the literature convinces me that protruding premaxillæ have never received the careful attention which has marked the investigations of surgeons in treating other physical defects. Some authors advise excising the bones; others advocate closing the lip over them when possible; still others advise removing a V-shaped piece from the vomer, moving the bones back and closing the lip over them. We often find the vomer divided, the premaxillæ moved backward, the cleft lip closed and no effort made to freshen, approximate and stabilize the bones.

Protruding premaxillae, separated as they are

from the maxillæ, should be considered as a recent fracture and so treated. *Under no circumstances should the premaxillæ*, even though they amount to only a small tubercle on the tip of the nose, be

Fig. 1. Profile of patient with protruding premaxillæ.

removed. These bones, together with the teeth which they embrace, have an important function. They add symmetry and beauty and impart normal contour to the face. Their loss means prognathism with its unsightly deformity. The upper lip recedes and the nose becomes broad and flattened. The superior arch becomes contracted so that the upper teeth occlude on the lingual surfaces of the lower. The loss of these bones is always unnecessary, unsurgical and should be deplored. Neither should they be excised nor simply forced back (Fig. 2). Would a surgeon feel that his duty was well done in the treatment of a compound fracture of the femur if he crowded the fragments into place without removing the intervening tissue and then closed the external wound? Would he expect to secure bony union without the application of splints and without immobilizing the parts? Similarly, a nor-

mal maxillary arch can be secured only by treating the parts in the same manner as one would handle a fracture, i.e., remove intervening soft tissues and approximate the bony fragments.

The premaxillæ should therefore be moved into place after freshening the surfaces which are to come into contact. The compact bone should be removed and the freshened surfaces of cancellated bone placed in contact and immobilized. When this is done, the soft tissues covering the bones may be sutured with horsehair. To divide the vomer, move the premaxillæ back and make no attempt to unite them to the maxillæ, is unsurgical, cannot produce a normal arch and may be likened to the treatment of a fracture elsewhere without assuring bony contact and immobilization with resulting non-union. The wires should not be passed through the premaxillæ but anterior to them and beneath the soft parts.

Fig. 2. Result following the excision of the premaxillæ. Note contraction of upper lip and protrusion of the lower. (Author's case.)

An attempt to move the premaxillæ backward should not be made in a patient younger than three months, because the bones have not become sufficiently ossified to form well defined alveoli. Besides, the lateral surfaces of the teeth are often covered by the soft parts only. Obviously, the teeth at this early age may be easily displaced.

ADJUSTING WIRE SUTURES

Introducing the wires is not difficult for the surgeon who knows the technic. Passing the wires through the maxillary bones in the usual way anteriorly and posteriorly and adjusting the lead plates enables the operator to approximate the alveolar processes and at least one-third of the palatal plates of the maxillæ, moving and holding the tuberosities in normal position, so that when the soft palate is united it will be of normal length and flexibility.

Fig. 3. Illustration showing the position of the horizontal plates of the maxillæ and the vomer, as they usually appear in single cleft lip and cleft palate. b—b, alveolar processes; c—c, horizontal plates; a, vomer; e, separation of the hard palate as it would be if the horizontal plates were lowered; d—d, lines of descending arch.

When the posterior two-thirds of the maxillary plates are elevated at an angle of 45 to 75 degrees, their borders do not meet (Fig. 3). The abnormal elevation of the posterior two-thirds of the horizontal processes of the maxillary bones is lowered by means of the wires and lead plates (Fig. 4).

Criticisms have been offered by men inexperienced in using lead plates or without the opportunity to observe their proper use, that they are likely to produce necrosis of the bone. I have never had nor have I ever seen a case of necrosis of bone follow the correct use of lead plates. If it occurs it is due to defective technic. Recently a patient returned to me who had worn these plates for two years, without the slightest inconvenience and without injury to the parts.

SPREADING OF THE TUBEROSITIES

I have spoken of the closing of the lip first as one means of approximating the separated bones.

The lip operation is one of the oldest in the annals of surgery, being described by Celsus, who was a contemporary of Tiberius (42 B. C. to 37 A. D.).

When the anterior part of the cleft is brought together either by the lip traction plan or by the single wire, the surgeon fails to give consideration to the consequent separation of the bones posteriorly. Every surgeon experienced in this work realizes that oftentimes these bones are widely separated posteriorly, due to the moving together of the anterior part of the cleft and action of the muscles and they cannot assume a normal position unless measures are employed to overcome this separation. The maxillæ act as levers, the malar processes becoming the fulcrums, and as the anterior ends of the maxillæ are drawn together the posterior ends move apart (Fig. 5).

Unless steps are taken in early infancy to prevent the tuberosities from spreading (as by the use of wires not only anteriorly but posteriorly) the bones will widely separate and the palate will be shortened to such an extent that perfect speech will seldom be secured. When the tuberosities are abnormally separated the soft palate, when united, will be put on the stretch and consequently shortened so that it cannot reach the post-pharyngeal wall; it will be like a drumhead without flexibility or resilience. If lateral incisions are made through the soft palate in an attempt to relieve the tension a great mass of cicatricial tissue will result, making

Fig. 4. Following the lettering of Fig. 3 as far as possible, for we have no a, to represent the vomer, b—b are the pinions of the bridge which correspond to b—b, the alveolar processes in Fig 3; c—c, correspond to the horizontal plates of the palate bones, misplaced upwards; d—d, lines of the descending arch which terminate in the meeting of the hemispheres of the bridge at e.

it thick, unwieldy and inflexible. It must be remembered that lateral incisions oftentimes divide the fibers of the tensor palati muscle, which has a two-fold function—that of making tension on the palate and dilating the pharyngeal orifice of the Eustachian tube during the act of swallowing. The result of the division of this muscle may thus lead

to early defective hearing, due to destruction of the continuity of the muscle and consequent failure of the normal dilation of the pharyngeal orifice of the Eustachian tube. When operating on the soft

length may be produced. (Figs. 6 and 7 contrast the two arches.)

IMPORTANT POINTS TO BE OBSERVED IN CLOSING PALATAL CLEFTS

My observation has been that function often has not been considered as an object to be attained. It seems that operators too frequently aim to close the cleft without achieving the all-important anatomical functional result. As I have said, function is dependent more on preventing the tuberosities from spreading than any other factor. When they *are* spread in young infants they must be narrowed to their normal breadth.

Moving the bones together in the anterior part of the cleft without attempting to prevent the tuberosities, which are oftentimes already abnormally separated, from further spreading contributes to the making of a short palate followed by defective

Fig. 5. Drawing showing change in position of the palate and alveolar processes due to either contraction of the orbicularis oris muscle after the lip operation or the result of moving the anterior alveolar processes together.

- a—a. Bones widely separated at birth.
- b—b. Posterior part of cleft at birth.
- d—d. Anterior part of cleft after alveolar processes are moved together but not united.
- e—e. Posterior part of cleft has widened. As the anterior part moves together the posterior part separates.
- c—c. The malar processes, the pivots upon which the leverage is exerted to move the posterior parts outward while the anterior parts are moved inward.
- f—f. The tuberosities widely separated as the result of failure to move them together or to prevent them from separating.

palate, the posterior wire should be passed as nearly as possible through the center of the tensor palati muscle as it swings around the hamular process, thus suspending the contraction of the muscle until the hemispheres of the palate unite.

I regret that I have not time to discuss the plastic surgery of the lip, the management of the defective nostril and the operation upon the nose, operations so important in rounding out the work of making normal these patients who are the victims of such distressing conditions. But what does it avail, to produce the most careful and painstaking operation on the lip, if underneath there is an improper foundation for this superstructure? There must first be provided a normal, well-rounded arch upon which to build a well-shaped lip and there must be a normal position of the tuberosities in order that a flexible, resilient soft palate of sufficient

Fig. 6. Cast showing the premaxillae removed, and extremely broad cleft of the palate. The distance between the buccal surfaces of the third molars is $3\frac{3}{4}$ inches. (Author's case.)

Fig. 7. Lower arch equally broad. Compare with preceding figure.

speech. Spreading of the tuberosities makes the palate too short and a palate too short makes the function of speech defective. The surgeon who permits the tuberosities of the maxillæ to spread,

Fig. 8. All wires and plates in position, maintaining the parts in quiet contact until union is accomplished. Lead plates, No. 13 American gauge, shown at sides, perforated for the passage of the wires.

thus making it impossible to secure a long palate, will meet with failure in his results and usually correct speech will be made impossible. In such cases, to make a palate that will reach the post-pharyngeal wall, a section of each of the palatopharyngeal muscles may be added to it.

When the bones are separated at birth, there is only one logical course to pursue, that is to freshen the surfaces that should be united as would be done with fracture of any other bone and approximate and immobilize the fragments. All general surgeons *do* so treat fractured bones. The *separated* bones of the palate should receive like treatment (Fig. 8).

To fail to unite the bones in early infancy usually leaves a deformity throughout life. A long, flexible soft palate, correctly functioning, is largely dependent upon a normal bony arch.

The surgeon, after operating on a soft palate in a youth or adult, finds the united palate tense and short. He reasons it is due to atrophy prior to the operation. It may be due in part to atrophy, but in a large majority of such cases spreading of the bones is an important factor in making the palate short, tense and drumhead-like.

The mattress suture is often valuable in the muscular tissues, but the interrupted suture is more

desirable in the muco-periosteum with an occasional mattress (end to end) suture.

Tension of the palate is relieved to a great extent by lowering it as far laterally as the hamular process instead of making incisions in muscular tissue (Fig. 9). Failure of union of the soft parts is often due to failure to properly denude the bones of the muco-periosteum and to improper suturing. An operator sometimes fails by making his sutures too tight. He must bear in mind that the tissues will not stand pressure and stretching; there must be relaxation sufficient to insure good circulation. Failure of union of the soft parts is sometimes due to the cutting out of sutures. The proper use of silver wires and lead plates will avoid this.

Fig. 9. The muco-periosteum is denuded from the bones of the palate as far back as the hamular process of the sphenoid bone. The flaps are then approximated and united.

The lead plates (Fig. 10) are not intended to be used for stretching the palate and pulling the edges together, but are to be used when the wires are inserted and the palate sutured—when the plates are put gently in contact with the mucous membrane and the wires twisted, but without tension. The plates are to prevent the sutures from cutting out and to hold the edges of the cleft steadily together. They also act as splints, so that when the palate moves it moves *en masse*. Dr. Hayes Agnew cut the tensor palati muscles to relieve tension. The wires and plates relieve tension without destroying the function of the muscles.

Extending over a period of forty years, we have read from time to time of devices—plates, et cetera—used to prevent the tongue from interfering with the newly approximated surfaces of the palate.

Fig. 10. Lead plates in position. They must be free from sharp corners and edges, and the wires not too tight lest the tissues be cut.

Their use, however, has been transient. The wires with which the lead plates are fixed are bent down in such a way that they do not lacerate the tongue but make contact of the tongue with them uncomfortable, thus avoiding disturbance of the palate.

It is the duty of the surgeon to see that the plates are properly adjusted. If they are not properly adjusted, if they are made too tight, if they are so placed that they will cut the tissues, failure is likely to follow.

The palate demands thorough cleanliness. Only by daily observation on the part of the surgeon and cleanliness on the part of the nurse, may the highest degree of success in treating cleft palate be achieved.

CONCLUSIONS

There are no operations in the whole broad field of surgery in which so large a percentage of failures occur as in palatal surgery. It must be remembered that the most careful operator, who has performed a perfect operation, may fail to secure a good result because of specific disease. Moreover, sometimes a most promising case coupled with the greatest care and perfect technic may result in failure on account of conditions beyond the surgeon's control.

The greatest obstacle in the way of success in maxillo-palatal surgery is a lack of knowledge of the correct age for the different steps and the methods of procedure. So long as the majority of

medical colleges utterly fail to teach their students this subject just so long will the principles underlying the surgery of the palate be misunderstood and, as in the past, there will continue to be innumerable failures in operations.

Those who operate on cleft palate only occasionally and the uninformed do not realize that maxillo-labio-palatal surgery is a vast field for study and practice. When we see mutilations, such as amputation of the premaxillæ, et cetera, which cannot be too strongly condemned, when we see that many without a knowledge of the fundamentals of the subject are continuing these practices, we feel that all measures available should be employed to stimulate the study of oral surgery and thus avert such calamities.

It must appeal to every surgeon, who logically looks upon the situation, that articles which have appeared in certain text books in the United States, England, France, Spain and some other countries, repeating the writings of authors of hundreds of years ago on the treatment of cleft palate, are antiquated and do not set forth the truths that have been revealed up to this period.

Fig. 11. Upper centrals.

The author of a text book assumes a great and solemn responsibility. Every child who is operated on by a surgeon whose knowledge in treating these cases was acquired by *reading* a text book with such teachings as the excision of the premaxillæ and consequent permanent mutilation of the patient, may well place the responsibility of this procedure at the door of the author.

DISCUSSION

DR. CARL W. WALDRON: It has certainly been a great privilege to be here tonight and hear Dr. Brophy give his experience during what is more than the span of lifetime of most of us here, an experience that has been fraught with many disappointments in some ways but yet always increasing and attaining more perfection.

Those of us who have made a study of Dr. Brophy's textbook will realize that tonight he has given us some ideas that are not incorporated in his textbook, particularly with reference to the time of the bone operation. I think eight or ten years ago Dr. Brophy was far more anxious to operate within the first week of life of the tiny infant than he is today. He has learned from experience that there is developed with the alveolar process greater protection of the developing teeth by waiting for a certain period of time, but not waiting too long; not waiting until the time when the process of molding, digital molding of the bones is made difficult by ossification.

This is one detail we might discuss for a minute—this matter of molding. Some of the observers, particularly Thompson, of Galveston, lay particular stress on this feature: during the operative procedure on the alveolar process, time should be taken; not too much hurry to insert wires, for instance. Take plenty of time to do what he calls digital molding, using plenty of firm, re-applied force to approximate the separated bony processes, and then hold them with the wires rather than to use the wires as a means of drawing them together. I think this is an important point. I feel that it has been so in my own practice. In taking care of these patients I take plenty of time to bring the parts together as well as possible with firm pressure of the thumbs. I might state that in my own experience the very process sometimes tires me out. My hands will ache for some time afterwards; it is somewhat difficult.

Dr. Brophy's emphasis of the importance of bony contact and immobilization is well taken. I feel that it is an important part of the operative procedure. There is one thing that might be mentioned and that is that I feel most anatomists agree that the smaller fragment in a unilateral cleft is in a relatively normal position as far as its lateral position is concerned, the displacement being an upward one of the palatal process. So in molding we must pay particular attention to the larger fragment to bring it over and approximate it to the smaller fragment and then hold it with the wiring.

I would like to ask Dr. Brophy one question with reference to bony union. Those of you who have read some of Dr. Ritchie's articles on this subject—and we are sorry that he is not here tonight because we would like to have him present his ideas on the question of preliminary lip closure—Dr. Ritchie says he has yet to see evidence of bony union as shown by the *x*-ray. I would like to ask Dr. Brophy if he has made any systematic record post-operatively, that is, three or four years after operation, of the presence of bony union by the use of dental films and careful *x*-ray studies.

There is another thing: this question of the single wire. I think if we are looking upon our wires as a means of approximation that the single wiring without the use of plates should be condemned; whereas if we carry out, as I described previously, the careful molding, in many cases a single wire if placed sufficiently posteriorly from the anterior cleft will suffice. I am sure that many men are getting excellent results by such a method. This problem of the spreading of the tuberosities also hinges upon the question of the placement of the wire and somewhat on the preliminary molding. I feel that it will not take place if

the molding has been done very carefully and the wires are put in carefully.

Now we have the problem of the soft palate—Dr. Brophy feels that the lead plates are essential in so far as the control of tension is concerned. I think Dr. Ritchie has added to our knowledge in the handling of the muscle problem in the lip and palate operations by his careful denudation, not by cutting away muscle but by a wide exposure of muscle fibers and the use of muscle sutures. I believe that to date he has had no muscle separation and no separation of the soft palate following operation. He has not to my knowledge resorted to the use of plates.

There is one important point in connection with the closure of the hard palate and that is that measurements should be taken. We should estimate for instance the distance from the alveolar process to the alveolar process just anterior to the position of the tuberosity, and then measure again the widths from that point to the margin of the cleft and determine whether there is sufficient tissue. If it is not there, wait for it to grow. We must figure that it is better in these cases to wait a year and if necessary make more extensive use of all our aids in the training of speech, and at the same time be sure of a closure; rather than to operate before for instance the fifteenth or sixteenth month of age and take a chance on the closure. It is much better, I feel, to wait for another year perhaps until we know by our measurements—say the measurements of a plaster cast that we can make from an impression—that we have sufficient tissue and can at least expect a closure at perhaps two operations, if not successful at the first attempt.

The question of the operative closure of the recurrent perforations was not taken up by Dr. Brophy. I feel that the delayed flap, which is a modification of the flaps we used a great deal in war surgery, is an advance in the hazardous undertaking of closing some of these recurrent perforations where the blood supply is not as perfect as we might hope.

I would like to ask Dr. Brophy where the special nipples may be obtained for use in feeding these posterior cleft cases, while waiting a year or two for the time for the operative closure to be performed.

In closing I want to again thank Dr. Brophy for the treat he has given us tonight and to assure him that when I go to Chicago I shall always call on him to see the good work he is doing.

DR. R. E. FARR: I would hardly have the temerity to discuss this subject in the presence of Dr. Brophy excepting that I wish to add a word regarding my esteem for Dr. Brophy and the work he has done. My notion for many years has been that cleft palate surgery began with Brophy and ended with Brophy. My feeling is that twenty or perhaps fifty years from now the work that Dr. Brophy has done will be much more appreciated than it is at the present time.

My experience is limited and yet a large percentage of the cases that have come to me have been operated upon by methods which Dr. Brophy does not and never has advocated. Generally these patients have been operated upon by the preliminary closure of the lip. Several years ago I showed four pictures of children from eight to twenty years of age with the forefinger of each lying in the cleft between

the bones, and these children had all had the lip closed within the first three months.

The whole question before us is: shall we repose the bone or not? This picture tells the story. Here is a photograph of a little baby before the wiring. A line down the center of the face cuts the ala on the side of the cleft about at the midpoint, that is, three-quarters of the way between one ala and the other. There is three-quarters of the nose on one side and one-quarter on the other. After the wiring, in every case in which we have been successful we have had an absolutely symmetrical face as shown in the next slide.

For many, many years Dr. Brophy has been kind enough to show me every detail of this operation. The only objection to it that I have is that it is more difficult in most people's hands than it is in the hands of Dr. Brophy. We have trouble with our anesthesia. We have difficulty in getting our landmarks, getting our wires high enough and far enough back. I think we too often tilt the bones.

This is the first time I have ever seen Dr. Brophy have time enough at a meeting to discuss the subject fully. I have not been where he has been the guest of honor like this, where he had the whole meeting and where he could discuss all of the points. I am certain that if his message takes root in this audience and his enthusiasm is transmitted to us he is going to save a great many children in the future from carrying these defects through life. Of course Dr. Brophy cannot do all of these operations. I wish to goodness he could. In regard to that last picture he put on the screen in which the lips had been stretched to such an enormous size I would suggest that a "lipectomy" be performed.

DR. BROPHY (closing): Replying to Dr. Waldron, I no longer operate upon patients a few days old and for the reasons he gives. The child should live long enough be-

fore operation to have all organs functioning well. I depend upon a pediatrician to get the child into proper condition.

I did not hear anyone state what other method could be used in the case taken from James Barry in order to close the cleft. Isn't it proper to bring the bones into normal position? I do not agree with Dr. Waldron that a single wire will accomplish the reposition of the bones. It will not hold the tuberosities in position and we know that the soft palate cannot be depended upon to do so. I should like to ask Dr. Waldron if, in his work, or that of Dr. Ritchie, where the anterior closure alone had been made, the soft palate after operation was long enough to reach the post-pharyngeal wall. If it is not the patient will not speak well.

The most eloquent answer that can be made to the question brought up by Dr. Waldron regarding whether or not bony union takes place may be had by referring to Figure 11. It is so certain that bony union does take place that I have never heretofore thought it necessary to offer concrete evidence. If it was necessary, thousands of such cases could be presented.

Dr. Farr has spoken kindly about the work I have been doing. I have simply tried to be conscientious and do the right thing and yet I have been criticised a great deal and some of my friends think that I should be in jail.

In conclusion, I feel certain that the man who makes a success of this work, bringing about a condition which will enable patients to go through life with the nose in the center of the face, a completely closed cleft and articulating distinctly, will not do it by using a single wire in the front. Personal appearance and function are the essentials. I am not particular how you obtain the results but have tried to show a method of meeting the indications. It is a notorious fact that cleft palate cases, the world over, usually fail to receive efficient treatment.

THE NEED

One newspaper is quoted as stating that the most important happening in this country last year was the birth of 2,000,000 children.

How many of them lived? This is not known accurately, because there remain eighteen states which do not yet register their births! Of the thirty states in this country within the Registration area, one child in every thirteen born dies during its first year. If the same ratio applies to the states which do not register, we have a total loss of 190,000 American children a year.

That is startling, but it is a long way from the day when parents were considered fortunate if they were able to bring up two out of every three of their children.

Still, it leaves us behind five other nations, including New Zealand, the best off of all countries which keep books on their greatest asset, which loses only one in twenty of its children during the first year.

But there are things almost as bad as death. There are children unfitted or not half fitted for life. And there are hordes of them just enough handicapped physically or mentally to be drawn into the ranks of those who may labor long but receive little happiness or substance.

Here are some of the handicaps: The figures may be taken as approximately correct:

Studies made in many communities indicate that millions of American school children suffer from malnutrition or physical defects, most of which can be prevented and many of which can be corrected.

They range from seventy-five per cent with dental defects to one-half of one per cent with organic heart trouble, in between coming those with tuberculosis, defects of vision, etc.

Then, as to mothers:

According to the United States Census Bureau, 17,800 women in the United States of America died from conditions caused by childbirth in 1919. In 1920 the rate rose to eight per cent. Italy, crowded as she is, has a rate of only five per cent lost mothers.

Sixteen nations save more mothers than we do.

To focus attention upon the above facts, without at the same time attempting to indicate some of the ways out, would be of little service. May Day, which is celebrated by children in many communities, perhaps offers the best opportunity to combine incentives to increased outdoor life for children with efforts toward a knowledge of what to do next in Child Health and Child Health Education.

FACTORS OF SAFETY IN GASTRIC SURGERY*

DONALD C. BALFOUR, M.D.

Section on Surgery, Mayo Clinic
Rochester, Minn.

The general principles of surgical treatment are more or less established, but the results of the application of these principles vary considerably in the hands of different surgeons. Operative mortality is always the first question in the mind of the patient to whom operation is advised, and, while it is of secondary importance in certain life-saving emergency operations and in malignant disease, it is of first importance to both patient and surgeon in operations of election. Remarkably low operative mortality rates are now possible in various fields of major surgery, even when the surgeon accepts his full responsibility and does not sacrifice the interests of the patient to a desire for low operative mortality records.

In surgery of the stomach and duodenum, the question of operative mortality is one of supreme importance because of the frequency of non-malignant conditions, such as duodenal ulcer, in which operation is carried out to relieve serious symptoms and not to save life, except in the occasional case. The safety with which operation for such conditions can be performed is shown by Moynihan, who reports nearly 600 consecutive gastro-enterostomies for chronic duodenal ulcer without a death. It is important, therefore, that surgeons keep such achievements in mind and become thoroughly familiar with the factors of safety which make such accomplishments possible.

The first factor of safety is concerned with the indications for operation, the risk which the operation entails, and the measures which may be employed to lessen the risk. In non-malignant surgical lesions of the stomach (chronic ulcer) the advisability of operation is usually clear, and comparatively rarely do real contraindications exist. Experience has shown that all chronic gastric ulcers should be operated on without unnecessary delay, because the risk of operation, which should not be greater than between 2 and 3 per cent, is insignificant compared to the danger of a permanent disability,—a disability which not infrequently progresses to a fatal outcome. In the few cases in which operation was not advised, other conditions such as

tuberculosis, nephritis, or cardiac disease, were so advanced as to prohibit an operation of election, and surgical treatment was postponed in the hope that the patient's condition might sufficiently improve, under treatment, to permit operation for the ulcer later with a reasonable degree of safety. In duodenal ulcer, neither the disability nor the danger of serious outcome is sufficient to warrant advising operation with the same emphasis as in gastric ulcer. Nevertheless, experience has again shown that the low risk of operation, 1 + per cent, and the excellent results of surgical treatment properly carried out leave no justification for non-surgical measures ineffectively prolonged. Complications such as hemorrhage, perforation (acute and chronic), obstruction, and malignant degeneration remove any doubt that may exist as to the necessity of operation. Because duodenal ulcer is a much less serious condition than gastric ulcer, factors which would have little or no weight in considering the advisability of operation in gastric ulcer attain considerable importance when duodenal ulcer is present. Consequently, contraindications to operation are seldom found in gastric ulcer, while in duodenal ulcer it is not uncommon to find that the circumstances justify postponement of operation. Various reasons are noted for advising against, or postponing, operation in cases of duodenal ulcer, such as extremes in age, short history, mild attacks at long intervals, positive x-ray findings without symptoms, marked obesity, serious cardiac, pulmonary, or renal disease (the ulcer being only an incidental finding), and the occupation of the patient. Selection of cases, therefore, is based not only on the operative risk, but on the severity of the symptoms and whether they respond sufficiently to medical management to keep the patient comfortable and self-supporting.

In malignant lesions (carcinoma) an entirely different problem exists, because the only hope of saving the life of the patient is by operation. Risks which would be quite unjustifiable in cases of non-malignant gastric lesions become justifiable in cases of malignant lesions. The surgeon, with increasing experience, is led to accept greater and greater risks in cases of gastric malignancy, because of the hopelessness of the disease without surgery, and because he is able to recall unexpected successes in cases in which there appeared to be little or no chance to remove the growth. As a consequence, it is difficult to keep the operative

*Read before the Annual Meeting of the Minnesota State Medical Association, St. Paul, October 10-12, 1923.

mortality of gastric resection for carcinoma under 10 per cent, and the mortality rate could probably be reduced one-half, if only patients in good condition and with moderately advanced lesions were accepted for operation. In cases of cancer of the stomach, unless the disease is obviously incurable because of metastasis, the conscientious surgeon must, to a considerable extent, follow the wish of the patient, a practice which does not contribute to a low mortality rate. Although radical operation is seldom indicated if there is metastasis, it should be noted that patients may live three or even five years after the removal of cancer of the stomach, which is already associated with metastasis to the liver.

A decision as to the advisability of exploration in cancer of the stomach has been greatly simplified by the radiologic examination. In the Clinic, Carman and his associates have graded gastric malignancy into three groups: (1) operable, (2) questionably operable, (3) inoperable. Of the operable cases, 50 per cent, so far as the growth was concerned, were found to be suitable for resection; of the questionably operable, 18 per cent; and of the few inoperable cases in which exploration was performed, 12 per cent were resected.

Patients with peptic ulcer do not, as a rule, require elaborate or prolonged preoperative preparation. If the condition is uncomplicated and the patient is in good general health, operation may be carried out without delay. If complications exist, or have existed, preoperative preparation will be instituted according to the nature of the complication. Obstruction at any point in the stomach sufficient to cause a retention of 300 c.c. necessitates gastric lavage, repeated for several days until the washings are clear; the stomach is thus kept clean up to the time of operation. The administration of barium for fluoroscopic examination is to be avoided in all cases in which gastric retention is shown by the history or by the test meal. Water should be given routinely in cases of obstruction, the amount varying with the degree of dehydration. Patients with marked anemia due to recent or recurring hemorrhages should be put to bed, a bland diet established, and transfusions given until the hemoglobin has been raised to 50 per cent, if possible. When the patient ceases to respond to transfusion, even though his condition is not so good as is desired, further delay is useless and inadvisable. Operation during gastric hemorrhage should

usually be avoided, not only because of the added risk, but because such hemorrhage may occur in the absence of any recognizable mucosal defects and under circumstances which strongly suggest ulceration. Recovery is the rule following a single attack of hematemesis, and the exceptions to the rule would not have been saved by emergency surgery. The best practice in cases of gastric hemorrhage is to keep the patient under observation until recovery from the effects of the hemorrhage has progressed to its maximal point, or at least to a point at which operation can be carried out with reasonable safety. If the patient is recovering from the effects of one hemorrhage and another gross hemorrhage occurs, or if he is losing ground because of continuous oozing, and an ulcer is known to be present, transfusion, followed immediately by operation, is advisable. The recent publications of Finsterer, showing the results of operation for gastric hemorrhage, deserve careful consideration, and may ultimately modify our present views.

The anemia associated with gastric malignancy does not often respond satisfactorily to transfusion, and little or no benefit may be expected from it. Severe anemia in gastric carcinoma is an unfavorable sign, particularly when associated with edema. The preparation of the patient who has cancer of the stomach consists chiefly in restoration of fluids, cleansing the obstructed stomach, and limited rest, but no marked improvement can be expected from preoperative treatment, so that its prolongation is unnecessary and unwise.

The chief factors of safety are in the conduct of the operation itself. The question of the anesthetic arises first. It is difficult to prove by statistics the relative value of the various anesthetics. In the Mayo Clinic, local anesthetic does not appear according to statistics to be a safer anesthetic than ether, but comparison by statistics is unfair because local anesthetic is usually employed for the poor surgical risks, and ether for the good surgical risks. It is, therefore, true that the operative mortality under such practice is higher with local than with general anesthesia. There is no doubt, however, that local anesthesia, combined if necessary with a small amount of general anesthesia, is of less risk to the patient, and especially to the patient in poor condition. The early reports concerning the new anesthetic, ethylene, and our own experience with it, indicate that a step forward has been taken in the field of anesthesia.

The first rule of safety is that the operation should be completed as expeditiously as is consistent with careful work. Speed should not be carried to excess, nor should care in detail reach the point of fussiness. One of the characteristics of the good surgeon is that he does not underrate the relative importance of time and attention to detail, particularly hemostasis. Gastro-enterostomy, in the uncomplicated case, can be properly performed in twenty minutes, and partial gastrectomy can be performed in little more than half an hour.

The next factor to insure safety is the selection of the operative procedure best suited to the lesion. Operative mortality, or more often postoperative morbidity, can often be attributed to failure to make the proper selection. The best results in gastric surgery will be attained by the surgeon who is not only familiar with the indications for the various operations, but is capable of properly carrying them out. As illustrations of wrong selection of operation, one may cite: forcing a posterior gastro-enterostomy when adhesions obliterate the lesser sac of peritoneum, or fix the first loop of jejunum; mobilizing a pyloric or duodenal ulcer which has perforated and become adherent to the liver; failing to free an ulcer which has perforated posteriorly and become adherent to the pancreas; neglecting to excise the ulcer which has been associated with hemorrhage; failing to resect the large ulcer which is, or probably will become, malignant; and partial gastrectomy for malignancy so advanced that the diseased tissue cannot be entirely removed. Such errors may be made because of poor judgment, but mistakes such as anastomosing the stomach with the transverse colon or with the terminal ileum, are examples of errors due to ignorance or inexperience, or both.

Having selected the operation best suited to the particular lesion, the next and most important factor of safety is its proper performance. Any operation on the stomach should be so performed that gastro-intestinal function is well preserved. The fundamental principle in the surgical treatment of ulcer is adequate drainage. Whatever anastomosis is made, therefore, should be large, properly placed, and protected against subsequent interference in its function. A small anastomosis invites failure to secure for the patient the symptomatic relief he should expect, and not infrequently requires secondary operation. An anastomosis which is not at the most dependent part of the stomach

does not provide the best drainage, and is at least relatively inefficient. To prevent subsequent contraction of the anastomosis, it must be free; hence all anastomoses should be made through a wide opening in the mesocolon, and the opening in the latter closed by suturing its edges to the stomach in such a way that the anastomosis hangs well below the opening in the mesocolon. In cases of gastrojejunal ulcer, it is common to find the mesocolon fixed to the line of anastomosis, suggesting that such a relationship was a factor in the occurrence of the secondary ulceration. Of great importance from the standpoint of both safety and good results is the avoidance of tension. A gastro-enterostomy may fail because of too short a proximal loop, and a suture line may give way after an extensive resection because tension on the line of anastomosis has not been relieved by reinforcing sutures, or because some other method of restoring gastro-intestinal continuity would have been preferable.

Another most essential factor of safety concerns the control of hemorrhage. Postoperative hemorrhage after operations on the stomach may occur, but there is no doubt that serious bleeding from suture lines is unnecessary, and when it does take place from a cut edge of the stomach or intestine, the surgeon must accept the fact that it could have been prevented. If clamps are used, they should be loosened after the first row of sutures is placed posteriorly, and all vessels that can be caught and ligated are so dealt with. The anastomosing suture should be held taut and carefully placed without too much tissue intervening between the stitches, and, in regard to the latter point, especial care should be taken at each end of the anastomosis where it is occasionally a temptation to invert an excess of stomach or jejunal edge with one stitch. Postoperative hemorrhage may and does take place from an unremoved ulcer, and may be sufficient to cause death, but such cases are exceedingly rare; I have seen one in several hundred operations for ulcer. The surgeon should be able to feel certain, from the care he has taken in performing the anastomosis, that any postoperative bleeding is not from the suture line. Finally, the control of sepsis as a factor of safety is of relatively less importance, because infection from the contents of the stomach, duodenum, or upper jejunum is not likely. Nevertheless, it is significant that those who report the best results in gastric surgery are the most careful

in walling off the operative field by suitably arranged pads.

POSTOPERATIVE MANAGEMENT

The care of the patient after operation on the stomach or duodenum is first directed toward the prevention of pulmonary complications. Mortality after gastric surgery is usually due, directly or indirectly, to chest complications. Chilling of the body surface should be guarded against during and following the operation. Particular care should be exercised in moving patients from an overheated operating room, through draughty halls, and into a room where the temperature is several degrees lower than in the operating room. Pneumonia, due to aspiration of mucus, or vomiting during recovery from the anesthetic, is a real danger that can usually be avoided by strict postoperative attention. Fluids by rectum should be given routinely, and in serious risks should be augmented by hypodermoclysis. Fluids by mouth may be given twelve hours after operation in the ordinary case, but recent experience in providing absolute rest for the stomach by allowing nothing by mouth for a period of four or five days after operation, with the judicious use of morphin, has led us to adopt the practice. Undoubtedly, the convalescence is now easier than under former methods of treatment, at least following more extensive operations on the gastro-intestinal tract. This is especially true after extensive resections, where only a small portion of stomach remains, the distension of which by too much fluid would place a dangerous strain on the suture line.

Acute dilatation of the stomach, a serious postoperative complication if neglected, is promptly relieved by the use of the stomach tube. There should be no hesitation in passing the tube if there is any suspicion that an acute dilatation exists, and this may only show itself in a rapid pulse. If gastric retention occurs during convalescence, due to poor motility, the stomach should be emptied and kept so until it has regained its tone.

If oozing takes place into the stomach, gastric lavage with water of 120° is by far the most efficacious measure, and without danger if carefully carried out. Removing partially coagulated blood from the stomach enables it to contract so that normal clotting in capillaries of the mucous membrane may more easily occur. Such lavage may be repeated as necessary. Should obstruction at the anastomosis occur and not respond to lavage,

prompt entero-anastomosis should be performed. In any complication which may arise during convalescence, the earlier its recognition and the more prompt its treatment, the more successful is its control.

DISCUSSION

DR. A. C. STRACHAUER, Minneapolis: The consideration of the factors of safety in surgery is always very important and particularly so in the field of gastric surgery because gastric surgery is really major surgery. Then, again, due to the better results being obtained gastric surgery is increasing in quantity. The stomach operation has become of very frequent occurrence.

In my own practice I consider the pre-operative care and preparation of the patient of the very greatest importance; in fact, as important as the pre-operative preparation of the case for prostatectomy. This is not generally appreciated. I do not alone refer to the obstructed patient who is dehydrated, starving and on the verge of acidosis, but to the ordinary routine case of ulcer of the stomach or duodenum. It is a mistake to operate upon ulcers which are active, which phase may be appropriately termed a crisis. While the ambulatory treatment at times suffices, these people should usually be put to bed, preferably under the direction of a gastroenterologist or medical practitioner, and placed on an ulcer management regime. Response to any of the standard medical ulcer treatments is usually very prompt, and in a varying period of time the ulcer becomes inactive. Many active ulcers which are non-resectible, due to the surrounding area of infection and inflammation, when inactivated become safely resectible. The medical treatment also builds the patient up generally, with increase of resistance. The eradication of the ulcer not only greatly increases the percentage of cures, but protects the patient against the occurrence of hemorrhage, perforation and malignant degeneration. As a matter of fact the microscopic examination of simple benign ulcers every now and then shows the same to have been malignant. The post-operative morbidity of gastroenterostomy is in a large measure due to the mechanical activation of the ulcer due to manipulation and traumatization at the time of the operation. This is obviated by gentle handling of the structures and by resection of the ulcer whenever possible. I find that we are resorting more and more to transfusion in the preparation of our patients, not alone in the cases with hemoglobin below 30 per cent but in the individual with hemoglobin of 60 per cent or more who has the appearance of being asthenic. The latter patient is transfused so that he may receive the benefit of the "kick" that is contained in the transfusion and so withstand the operation better. All patients scheduled for major gastric interference are grouped for transfusion whether they require the same or not.

Employment of the trap door incision, that is, a combination of the transverse and the longitudinal incisions, giving the most ample exposure possible, is, in my opinion, a factor of safety in gastric surgery, particularly in attacking ulcers high up on the lesser curvature.

Dr. Balfour refers to pneumonia as a factor in carrying off these patients. I believe that the routine practice of

having the patients sit up with a back rest on the first day after the operation, or even on the day of the operation, is an important aid in decreasing the incidence of pneumonia.

Dr. Balfour has given this subject thorough consideration, and there is no occasion for my going over and enumerating all the various factors which he has so well called to your attention and sufficiently emphasized.

DR. ARNOLD SCHWYZER, St. Paul: When one hears this paper one feels that here a man of experience sits up and thinks: "What is really now the most important in all this gastric surgery? What can still improve the already splendid results?" As Dr. Strachauer says, there are so many things mentioned in this paper that one cannot go through them all; one can only emphasize a few. For instance, the value the Doctor laid on resecting gastric ulcers. That was brought home to me in a very vivid way in a recent case where we resected. Now I thought I had experience in judging pathological conditions. When I cut that resected piece open, I said: Here are two beautiful, fine, round ulcers, as classical as they can be, one with a diameter of a centimeter, the other considerably smaller. But when we cut through them, we became a little suspicious. The larger one was showing a little thicker base than we were used to seeing and microscopically it was a very plain carcinoma. That shows the good judgment in resecting all those cases of gastric ulcer.

The Doctor said in his paper that if a bad hemorrhage occurs after the operation, we have to consider ourselves guilty. I think in suturing with the continuous suture if one goes around the larger vessels, makes a loop around them, he can do much in preventing that.

In bleeding before the operation—I again can only emphasize what he said, that is, when it is necessary or desirable to transfuse, to do the operation immediately afterward; in fact, to leave the patient on the table and proceed to operate has seemed to me the most desirable. Especially those cases of small, continued, or frequently repeated bleeding, where even with a strictest diet we do not get stopping of the bleeding—I think with those we should not wait long before we go at them.

About the short loop operation the Doctor has mentioned—it always strikes me that there the main cause of trouble is the pulling of the no loop end, that is, the distal end. We then really stretch the anastomosis opening so that the upper end is the direct channel. I have long used a device to counteract vicious circle. When you make your gastroenterostomy, you make the outlet free if you make the sutures grasp a broader surface toward the upper end. With these wider sutures, you constrict the inlet, get a better and broader union at the upper end and produce a little kinking off of your inlet.

About postoperative pneumonia and respiratory difficulties. It is painful to hear the patients under ether in some hospitals—the noise they make with the mucus in the trachea. That of course is awful. The local anesthesia in gastric surgery is, as the Doctor said, a distinct step ahead, especially if we do not insist too much on it but use it with perhaps at times some ether. After the operation very often those patients fill up and then I have felt that it was a great help to use a little trick. I come

into a sick room and I see the patient would like to cough but he does not dare to cough on account of pain and he cannot cough. The only way to help these people is if I get a good hold of them on the sides of the abdomen near the field of operation, and ask them to cough. When they cough I press hard so that at the same time I not only help them to cough, but that relaxes the stitches and they can cough with hardly any pain. I have very often gotten out large masses of phlegm that they had there for hours and could not get rid of. I think I have saved the life of at least one patient by this. The nurse is instructed how to hold and how hard to press at the moment of coughing.

DR. WILLIAM J. MAYO, Rochester: I would like to speak of two points that were brought up in Dr. Balfour's paper: In case of a severe hemorrhage from ulcer, I think it is not wise to operate immediately following the first hemorrhage, since, if patients die from acute hemorrhages, they do not die usually until they have had the third hemorrhage. This was pointed out in the old pre-antiseptic days with regard to the secondary hemorrhages from infected thrombi. If, therefore, the patient has but one hemorrhage, I think it wise to wait. If they have a second hemorrhage as severe or approaching the severity of the first, I believe it is wise to transfuse, as Dr. Schwyzer says, on the table, and to operate at once. In operating there is only one thing to do, that is, open freely at the site of the ulcer and find the bleeding point. Gastro-enterostomy, as a rule, will not avail. The hemorrhage will usually be found coming from a short, straight blood vessel in the posterior wall, often in pancreatic tissue. About one ulcer in eight that bleeds before operation will bleed after operation. These are very trying cases. The rule now is that if patients relapse several times, it is wise to resect the pyloric end of the stomach, where the ulcer starts either on the duodenum or on the stomach.

We have been quoted a great deal with regard to the question of cancer on ulcer. Our experience is based, not on all patients that come to the Clinic with cancer of the stomach, but on the patients that are actually operated on for cancer of the stomach. We have been quoted as saying that 71 per cent of cancers of the stomach had their origin in ulcer. I doubt whether even 25 per cent of cancer of the stomach observed consecutively could be actually shown to have their origin in ulcer, but that ulcer of the stomach is a serious disease and more serious than ulcer of the duodenum, and that it often precedes cancer, we cannot doubt. The great life insurance companies were anxious to know whether patients on whom operation had been performed for ulcer of the stomach and duodenum were insurable, and Mr. Hunter, the Vice President of the New York Life Insurance Company, came to our Clinic and with his own actuaries investigated the records of about three thousand patients who had been operated on for ulcer of the stomach and duodenum. Then through the medical examiners of the life insurance companies, these patients were traced, and as far as possible examined; thus accurate data were obtained concerning the actual results. They were able to trace about 90 per cent of the patients, and found that five years after operation on the duodenum for peptic ulcer the death rate was, if anything,

less than that among the average insurable persons of the same age. The death rate five years after operation for ulcer of the stomach was two and a half times the normal death rate at the same period of the average insurable persons.

DR. THEO. BRATRUD, Warren: Dr. Balfour's paper could not of course cover the whole field of gastric surgery. There is one type of gastric surgery which I wish to comment upon. That is an acute perforation of the stomach or duodenum. We have had several consecutive cases without a death. In every one of these cases we performed a jejunostomy and closed the perforation. As I understand it, there is a great deal of dispute as to whether a gastroenterostomy should be done in an acute perforation or not. When jejunostomy is done you can pour in a pint of water into the bowel right on the operating table; or you can start feeding them the next day with milk and glucose and whipped eggs. And another nice thing about the jejunostomy in these acute perforations is that they have no distension of the stomach, and very few of them have to have any postoperative treatment for gas distension.

We had trouble with two out of nine cases where we did a jejunostomy in acute perforation. One had a gastroenterostomy about a year after his perforation, and the other one had quite a severe hemorrhage from the stomach. Another case on which we did a jejunostomy for acute perforation had had a gastrotenterostomy some twenty years before for duodenal ulcer. At the time of the operation we found a large duodenal ulcer right under the pelvis of the gall bladder. We found the gastroenterostomy functioning properly, in perfect condition. This man was sixty-five years old. His convalescence was perfect.

I think the Doctor called attention to the large ulcer on the lesser curvature. We had one case with a high ulcer that we used the Balfour cautery and found so wide an ulcer after exposing that a sleeve resection seemed necessary and I presume that is what Dr. Mayo would have done under the circumstances. The man was not in very good condition, and we did a jejunostomy and we fed him through a tube for six weeks. He gained a great deal in weight. He had suffered so much pain prior to his operation that we were afraid of operating on him—we had examined him very thoroughly—for fear he had some spinal tumor on account of his severe pain. But this man was so satisfied with the tube that he was unwilling to have the ulcer removed when we took the tube out. He has gotten along nicely now for two years.

DR. A. C. STRACHAUER, Minneapolis: I am very glad that Dr. Bratrud brought up the question of the surgery of the perforated gastric ulcer. I must say that a great deal of harm has been done by the teaching in which gastroenterostomy is recommended routinely in cases of perforated gastric ulcer, particularly in the hands of the general practitioner and in the hands of surgeons of limited experience working under situations and circumstances that are not the most auspicious for the performance of gastric surgery. I want to go even one step farther than Dr. Bratrud, my opinion being based particularly on two cases that I had the opportunity to come in contact with

this last year. First, let me say that the indication as far as surgery is concerned in the perforated ulcer is to "get in and get out." It is my own practice simply to close the ulcer, resecting the margin if necessary to get a good closure. But anyone with experience in a perforated gastric ulcer knows how extremely difficult it may be to suture the wall of the stomach beyond the ulcer. It is inflamed; it is infected. Sutures do not hold; they pull through just like through cheese.

This last year I had the satisfaction of seeing two cases, operated upon out in the smaller towns, in which the general practitioner had the good judgment to open the belly, stick a rubber tube in the perforation opening in the stomach, put in a stitch or two, and close the belly and be satisfied with it. The thing to do is to get in and get out. Do not do too much. I know to my own satisfaction that it is unnecessary to perform the gastroenterostomy.

DR. DONALD C. BALFOUR, Rochester (closing): I appreciate very much the discussion of this paper. One of the points deserving emphasis was that made by Dr. Strachauer regarding the inadvisability of operating on patients with gastric ulcers when they are very ill, that is, when they are going through an acute exacerbation of symptoms. The remarks that Dr. Schwyzer made about the resection of ulcers could also be especially emphasized. Certainly, the nearer one can approach a routine resection of a gastric ulcer, the better will be the results. Dr. Schwyzer also has drawn attention to the necessity of avoiding tension on the suture line and described his simple method of doing so.

I might supplement what Dr. Mayo said about the study made by the Actuarial Society to this extent: the first thing that comes to one's mind when he learns the result of this study is, "What was the cause of death in patients who died following operation for gastric ulcer?" As Dr. Mayo said, the patient who has been operated on for duodenal ulcer was shown by actual figures to have a little longer expectation of life than one of similar age and sex in the general population group, and in gastric ulcers the subsequent death rate was about two and a half times as much.

I took occasion, when this report came out, to investigate as well as I could the cause of death in the latter group, and it was astonishing to learn of the number of patients who had died of cancer afterwards. And then as you review the operative records of those patients who had died of cancer, you will find that a large proportion had had only a gastroenterostomy done for a large, irremovable lesion, presumably gastric ulcer. The lesion was usually attached to the pancreas, and the surgeon felt that it was not possible, or not feasible, to attempt to get a section of it. Those patients did well for a few months, then began to lose ground, and a report came within one or two years that they had died of cancer. It is reasonable to suppose that they had cancer at the time they were operated upon. If one eliminates that group from the entire group of patients who have died after operation for gastric ulcer, he will find that the expectation of life is very much better than was found by the Actuarial Society.

I would also like to add my compliments to Dr. Bratrud for that excellent suggestion of jejunostomy in the treatment of perforated gastric ulcers.

SOME PHASES OF THE GLAUCOMA PROBLEM*

WILLIAM H. WILDER, M.D.
Professor of Ophthalmology,
Rush Medical College
Chicago

The observation that the condition of glaucoma is so frequently overlooked not only by the general practitioner, but also by men professing to practice ophthalmology, and even when recognized or suspected, is so frequently neglected or imperfectly treated, has prompted me to offer a few remarks on this subject that has been such a favorite theme for study and writing of ophthalmologists.

There is so much to say on such an important topic and all that is known of it has been presented in the literature so much more ably than I can hope to do, that it is with some hesitation that I venture to offer it as the subject of a paper that your chairman has dignified on the program as an address.

It is only because of the hope that some observations on the subject that have been impressed upon me after considerable study of such cases and experience in their treatment, may stimulate some of the younger men to more careful study and examination of this really difficult subject, that I feel justified in presenting it before your society.

In considering the subject of glaucoma we should get away from the idea that has so long obtained and that is still held in most text-books, that we are dealing with a disease entity.

While glaucoma is indicative of an abnormal condition of the eye, it is more accurately a syndrome, a symptom complex, the chief feature of which is intra-ocular pressure.

The accumulated experience and observation of many students of this subject demonstrate the complexity of the pathologic condition that may underlie glaucoma.

The division into inflammatory and non-inflammatory, acute, sub-acute and chronic or simple forms is the natural sequel of considering the condition as a disease *per se*, and is confusing. Much to be preferred is the simpler nomenclature of congestive and non-congestive forms adopted by Elliot and other writers on the subject. Non-congestive

forms, as we know, may, under favorable conditions, become congestive.

Hypertension, increased intra-ocular pressure, is universally recognized as the dominant feature of this condition and the one that demands our closest attention in the study and treatment, but underlying this may exist pathologic changes and conditions so diverse and complex as to defy our efforts to elucidate them.

PROBLEMS OF ETIOLOGY

In the study of the etiology of glaucoma we are confronted with difficulties from the outset. A knowledge of Pathological Anatomy assists in the study of pathogenesis. In this subject, the lack of material for studying the earliest stages of glaucoma increases our difficulties. Most of the glaucomatous eyes that come to section are those in the latest stages, and we are not warranted in concluding that these conditions found are those of cause and not of effect.

I assume we are all familiar with most of these changes or at least with the most prominent ones.

The shallow anterior chamber, the filtration angle blocked by the root of the iris, the atrophied iris, the swollen ciliary processes, edematous cornea, the engorged ciliary vessels, the cupped optic disc, the cavernous atrophy of the optic nerve, all these and more have been accurately and carefully observed. But it is difficult to answer the question: "Are these the cause or the effect of the increased intra-ocular pressure?"

There is little doubt that age is an important factor in the etiology. It is a common observation that most cases of glaucoma occur in middle and late life, and statistics confirm this.

For instance, in the analysis of a series of 1,032 cases of primary glaucoma Haag found that four occurred in the first decade of life, 16 in the second, 26 in the third, 74 in the fourth, 176 in the fifth, 288 in the sixth, 329 in the seventh, 116 in the eighth, and three later.

These figures are in accord with the observations of Priestley Smith on a series of 1,000 cases collected from the practice of a number of surgeons.

But in what way does age influence the intra-ocular pressure? Priestley Smith, one of the most profound students of this subject, has shown that the lens grows larger with advancing life while the size of the eyeball remains the same or possibly becomes somewhat smaller. He claims to have demonstrated that the ciliary processes are more

*Read by invitation at the meeting of the Minnesota Academy of Ophthalmology and Oto-laryngology, St. Paul, Minn., Jan. 17, 1924.

prominent and bulky in the old than in the young. With the increase in size of the processes and the lens, the circumlental space is correspondingly narrowed so that fluids cannot so readily pass from the vitreous into the aqueous chamber.

In consequence the lens and swollen ciliary processes are pushed forward against the iris, the root of which blocks the filtration angle and thus impedes or stops the outflow of fluids through the spaces in the pectinate ligament. Of course this would explain the shallow anterior chamber which is one of the well recognized signs of an established glaucoma.

Thickening or sclerosis of the fibers of the pectinate ligaments as pointed out by Henderson may contribute to this result. As a consequence of such thickening, which may be one of the manifestations of fibrosis incident to advancing life, the lymph spaces in this structure may be seriously contracted so as to be inadequate for the circulation of lymph.

Valuable as is the knowledge of these factors in the production of glaucoma, the ultimate cause is not yet known. What brings about the enlargement of the ciliary processes? Is such an enlargement in the nature of an inflammatory condition? Is there associated with it an increased secretion of fluids which the circulatory system of the eye is unable to take care of, thus raising the intra-ocular pressure? If there is an increase of fluids in the eye are they in any way changed in their physical or chemical nature? What rôle do vaso-motor disturbances and nervous irritations, so common in the period of life when glaucoma occurs, play in the problem? Do degenerative changes in the uveal tract, particularly the ciliary body, bring about increased or altered secretions in the eye? What influence do various morbid states that result in auto-intoxication have in bringing about such degenerative changes in the ciliary body?

These and various similar questions are engaging the attention of the students of the subject and have not yet been satisfactorily answered. Possibly they may never be answered, associated as they are with some of the most intricate problems of metabolism.

In truth, the etiology of glaucoma is hydra headed. In the last few years writers on the subject seem to have found reasons for denying any causative relation between arteriosclerosis and glaucoma. One cannot escape the thought, however, that a condition like arteriosclerosis that so profoundly

affects the welfare and nutrition of tissues, may play a rôle in bringing about degenerative changes in the eye, particularly if the ocular vessels are so affected, that may lead to the results that we are considering, viz.: hyper-secretion of fluids and alteration of such secretions. Of course, this is, at present, mere speculation.

Appropriate in this connection are the admirable words of the late S. D. Risley on the subject of Etiology: "Glaucoma is a disease, coming on at an age when wear and tear, harassing vicissitudes, misfortunes, exposures, overwork and vicious living have sapped the physiologic foundations of life; when infections have found entrance to the structure of the organism through the doorway of the epithelium; and when a variety of toxic, auto-intoxic and other influences have set up vascular and cardiovascular disease, associated nephritis, uveitis, high blood pressure, etc. Glaucoma, in fact, rarely occurs in individuals in good general health."

DIAGNOSIS

The diagnosis of congestive glaucoma should not be difficult even in the early stages, when we consider the distinct signs that it presents. And yet we can all recall deplorable cases that have been overlooked by the optometrist, and also by the general medical practitioner, in which the eye has been greatly jeopardized or possibly lost in consequence of such an error. Ignorance in regard to this dreaded condition should not exist. General physicians should be impressed with the importance of the early recognition of it, and, although they may do no ophthalmic work, should be able to recognize it, or at least in more insidious cases to suspect it and to refer the case to the specialist for exact diagnosis.

Errors of recognition are not necessarily due to ignorance, but may result from oversight because of the multifarious duties the general practitioner must assume. I recall a recent case under the care of a physician of no mean attainments, which was being treated for persistent vomiting. The eye had distinct congestive glaucoma, but was not painful although the sight was much impaired.

Such experiences are not uncommon and suggest the importance of impressing upon the general physician the necessity of examining the eyes as a part of his general examination of a case. This would be borne home to them if they realized that

at least one per cent of the cases in an eye clinic or in private practice are glaucoma.

No difficulty should be encountered by the specialist in the diagnosis of congestive glaucoma especially if it is once established or is in an acute stage. The signs and symptoms, all produced by the increased intra-ocular pressure are so familiar to us that they scarcely need more than enumeration on this occasion. Steamy, insensitive cornea occasioning rainbow phenomena around lights; faint ciliary congestion in acute stages and engorgement of ciliary veins that penetrate the anterior portion of the cornea; shallowing of the anterior chamber and oval enlargement of the pupil; more or less haziness of the media in consequence of which and also in consequence of the pressure on the retina there develops impairment of central and peripheral vision; if the condition has existed for any length of time, more or less cupping of the optic disc with possible pulsation of veins or arteries or both; in the acute stages, because of the haziness of the media, impossibility of seeing the details of the fundus; pain of varying degree, according to the intensity of the acute attack, sometimes in the eyeball, sometimes simulating a facial neuralgia, or occasionally dull and ill defined, or of a nature to reflexly excite nausea and vomiting; marked hardness, increased tension of the eyeball as determined by palpation or with instruments; all of these signs and symptoms form a clinical picture that the specialist readily recognizes as acute or congestive glaucoma.

There may have been prodromal signs before the attack, but the glaucomatous condition even then must have been present. I like the classification of stages used by Elliot of early glaucoma, established glaucoma, and late glaucoma, instead of prodromal, acute, chronic and absolute of most writers.

It is in the non-congestive forms of glaucoma that problems of diagnosis present that are often difficult to younger practitioners in ophthalmology, particularly in those cases of so-called simple glaucoma, in which the intra-ocular pressure is not at all times measurably increased. These are the cases that frequently puzzle us in diagnosis and raise questions as to treatment. Frequently they present little or no impairment of central vision; the onset of increased intra-ocular pressure has been insidious and its progress slow. The first intimation of anything wrong may be the discovery

in the routine examination of a cupped disc, and then further examination elicits the glaucomatous condition. Or the patient may complain of dull pain, again of neuralgic pains in and around the eyes at times, blurring of the vision when reading as if his glasses do not fit. Such symptoms may indicate disturbances of accommodation from congestion of the ciliary body, or disturbance in the refractive power of the lens from increased pressure. It may occur in myopes as well as hyperopes.

Probably in these cases of so-called simple glaucoma the increase in tension is not constant, but intermittent. Before the days of more accurate testing of tension with the tonometer, there was question as to whether many of these simple glaucomas manifested any increased tension, it being too slight to be noted by digital examination, but careful tests with the tonometer reveal that, at times, increased tension exists.

It is in such cases that we must arrive at the diagnosis by a study of the visual fields, the central vision, the appearance of the optic disc and a record of the tension as taken with the tonometer at various times.

The fields for white and colors, particularly red and green, should be taken, not once, but frequently, to record the progress of the case. They should be taken by the same observer each time, and as far as possible under the same conditions as to light, environment, background, etc., for there is no examination that admits of a greater chance for error on the part of both patient and observer than a perimetric examination of the visual fields.

We are all familiar with the various irregularities and contractions of the fields that present in simple glaucoma, but certain features stand out prominently enough to make definite characteristics. The contraction of the field is usually, although not invariably, found on the nasal side. It may be more marked above or below, depending upon the pressure upon the optic nerve. It is my opinion that the position of the physiologic cup, whether central or temporal, may determine in the beginning the character of the shrinking of the visual field. It is well to record in our histories, in routine examination of cases, a brief description of the position, size and depth of the physiologic cup for future reference and comparison.

With the continuance of the intra-ocular pressure the contraction of the visual fields proceeds until final blindness is reached. The color fields

usually contract concentrically with the field for white, but atrophic processes in the optic nerve may alter this rule.

The blind part of the field, sooner or later, is found to be in contact with the blind spot of Mariotte as first pointed out by Bjerrum, and both relative and absolute paracentral scotomas of Seidel may be demonstrated merging with the blind spot of Mariotte.

To map out these defects one must use small objects of 1 mm. or 2 mm. on a Bjerrum screen or the excellent instrument devised by Dr. L. C. Peter, the campimeter, which I find convenient. Lloyds' stereocampimeter, made by Bausch and Lomb, is even more useful in cases that have binocular single vision. The discovery of Bjerrum's sign and the scotomas of Seidel doubtless furnish valuable testimony in the diagnosis of early glaucoma, but, as has been said, it is a method of examination that must be accurately done to avoid error.

TONOMETRY

We must always hold to the central feature of glaucoma, increased intra-ocular pressure. Without increased pressure there could be no glaucoma; with it, all the manifestations of glaucoma may present, depending upon the degree and the continuance of the pressure.

In simple glaucoma, the pressure may not be great, but it may be continuous. In some cases it may not be continuous, but may be intermittent.

The tonometer enables us to determine this with more accuracy than can be obtained with the fingers. Furthermore, a record of observations can be made so that comparisons can be made from time to time as to the condition of the pressure, which could not well be done with digital examinations.

In this lies one of its great values.

With any form of tonometer errors may arise from inaccuracy of technique, and with any of them, however carefully calibrated they may be on the basis of manometric measurements of normal intra-ocular pressure, there will be variations in results arising from such conditions as rigid or flaccid cornea, slight keratoconus, high astigmatism, regular or irregular, corneal scars, etc. Its value is a relative one. It may or may not give us an accurate reading of the intra-ocular pressure in terms of millimeters of mercury, but it will from

day to day or week to week, if properly used, give us on the same patient the relation of impressibility of the eye to intra-ocular pressure.

My preference is for the Schiotz instrument because of its lightness and accurate construction. The patient should be lying flat on the back, so that the face may be in the horizontal position. One per cent holocain or butyn solution is used to cause anesthesia of the cornea. The patient is asked to fix some object on the ceiling so that the instrument can be placed exactly vertical on the cornea, the foot plate occupying the exact center of the cornea. Failure to do this will give inaccurate readings. I have noticed that two may work together to good advantage, one holding the instrument and keeping the patient's gaze in the right direction while the other makes the reading.

The instrument should be tested on the artificial metal cornea frequently, to be sure that the indicator arm registers accurately at zero on the scale. The instrument must be kept in perfect condition, so that the plunger glides easily.

Numerous observations seem to indicate that the normal limits of pressure seem to be between 15 mm. and 26 mm. on the Schiotz scale, but there may be individual cases where 28 mm. or even 30 mm. is normal.

PROBLEMS OF TREATMENT

Here we are confronted with difficulties that arise from our lack of definite, accurate knowledge of the etiology. Assuming the correctness of the statement of Fuchs that "genuine glaucoma develops only in an eye which has a predisposition to it," a dictum with which many will agree, the question naturally arises: What constitutes such a predisposition? If we knew exactly we should be on the way toward a rational prophylaxis. Lacking this definite knowledge we are forced to fall back on therapeutic measures that are largely empiric.

Most of these measures aim at combating some of the body conditions that are supposed to contribute to the development of glaucoma. In general they are reasonable for they include such measures as avoidance of excesses in diet and drink, avoidance of worry and hurry, prolonged hours of work and exhaustion, etc., etc., prescriptions that are not easily filled by many patients.

Few people realize the sagacity of the advice of the old medical philosopher that the best physicians to call in are Dr. Diet, Dr. Quiet and Dr. Merri-

man. As to our local therapeutic measures, they are all directed toward the main feature of the condition, the increased intraocular pressure, and are intended to facilitate and promote drainage from the eye.

We use myotics such as eserine and pilocarpine, and they have unquestionably shown their efficiency in a degree. The salicylate of eserine seems preferable to the sulphate, for it seems less irritating, and for continuous use in simple glaucoma, pilocarpine muriate or nitrate is to be preferred because of its less irritating effect on the iris.

The stretching of the iris resulting from the marked contraction of the sphincter muscle must draw the root of the iris away from the filtration angle and allow better circulation through that part. For the same reason the spaces of the iris are opened up and are supposed to be better able to absorb fluids from the anterior chamber.

One of the most important problems of treatment is that concerning operation, and particularly concerning operation on non-congestive or simple glaucoma. In congestive cases the evidence is clearer, for the accumulated experience of the masters in ophthalmology from Von Graefe down to those of present times speaks loudly in favor of operative means to counteract the increased intraocular pressure.

The debate waxes warm at times in regard to which method has the greatest value, and iridectomy still seems to have the best of it, but there seems to be little dissent from the view that some operative measure is necessary to bring about an artificial drainage.

It is different in the case of simple or non-congestive glaucoma. Here we have a condition that does not present the immediately dangerous features of the congestive type, and there are those

whose experience and skill are great who maintain the inefficiency of operation and rely upon the powers of myotics and general measures to maintain the proper pressure equilibrium.

How are we to direct our way in the midst of such disagreement? It seems to me that the study of our cases by means of the tonometer and the visual fields must furnish the guide. It may not be amiss to refer to my own rule of practice in such cases.

If the case can be controlled and general measures and regular applications of pilocarpine will keep the tension within normal limits, if the contraction of the fields does not continue, the central vision remaining normal, operation is not urged, but the patient is informed of the importance of regular observation of the case and religiously regular treatment. My observation is that cases that can be controlled in this way are few. If, in spite of general treatment and regular use of myotics, the records of the tonometer show increased tension at times, even if not great, and the fields slowly contract, or show enlarging scotomas, even if central vision is normal, operation is advised and urged, the patient, so far as his intelligence will permit, being made acquainted with the condition and its dangers.

As to the method of operation to be employed to accomplish this artificial drainage, the time at my disposal will not permit a discussion.

As in the past many roads led to Rome, so here many methods of operation properly performed have brought about the desired result and will do so again if proper conditions obtain and they are properly performed. The operations that have been proposed and championed for this deplorable condition are so numerous as to indicate that the perfect one has not yet been devised.

HEADACHES FROM THE STANDPOINT OF THE OPHTHALMOLOGIST*

PAUL D. BERRISFORD, M.D.
St. Paul

No symptom in medicine is more prevalent than headache and few there are, indeed, who at some time or other have not been victims of it. When viewed from an ophthalmological standpoint headaches due to eye strain must of necessity be differentiated from other types of headaches with which they are most readily confused, and it is this point that will be particularly emphasized. However, headaches due to more general causes such as diseases of the brain, digestive tract, kidney, blood vessels, acute and chronic infections, intoxications (chemical), constitutional diseases, etc., should never be lost sight of.

In the experience of the oculist, eye strain is the most frequent cause of headache. The complaint is probably due to the effort of accommodating in the presence of a refractive error or maintaining single vision where a muscular imbalance exists, thereby producing a neuro-muscular tension. The exciting cause may be hypermetropia, hypermetropic astigmatism or more rarely myopic astigmatism, esophoria, exophoria or hyperphoria. As a rule headaches of ocular origin are associated with the use of the eyes for near work, having their onset in the afternoon or evening, and are relieved by sleep or a period of rest. Nevertheless there are cases in which this symptom appears upon rising in the morning and becomes steadily worse throughout the day, especially where a muscular imbalance exists. Headaches due to eye strain are usually supraorbital or frontal, less commonly occipital or vertical. It has been the experience of some observers that, in a general way, headache in the frontal region is due to hypermetropia, in the temporal region to hypermetropic astigmatism and in the occipital region to muscular imbalance. So nice a selection can be justly challenged. The character of the pain is most frequently of a dull or boring nature and almost always bilateral and of equal intensity. In extreme cases even nausea and vomiting may be complained of.

A small degree of hypermetropia or hypermetropic astigmatism is physiological for the human

race and ordinarily gives rise to no symptoms. Even low degrees of muscular imbalance may be borne without discomfort. Nevertheless, the presence of a refractive error, however small, may, in certain individuals, be productive of the most annoying symptoms which, when optically corrected, are completely relieved. When a small refractive error or muscular imbalance produces eye strain there is always an additional etiological factor coupled with it, such as an unstable nervous system, lowered vitality from whatever cause or the excessive use of the eyes for near work. Such minor ocular derangements so frequently produce symptoms of eye strain in librarians, stenographers, bookkeepers, et cetera, that one might call it an occupational disease in this class of workers, due, no doubt, to prolonged reading, changing the gaze alternately from one near object to the other or faulty illumination.

There is a type of patient who, after a motor ride, shopping or moving picture entertainment, complains of pain in the eyes and base of the skull, the so-called "panorama headache." Usually, ophthalmological examination shows only a small degree of refractive error or muscular imbalance—more particularly the latter. In the opinion of the writer such cases are characterized by nervous instability.

Through medical inspection in public schools, much light has been thrown upon the causative factors in the production of apparent eye strain in children. The writer, during a service of seven years at the St. Paul Free Eye Dispensary, has retinoscoped 4,000 such cases, the usual complaint being difficulty with near work, e. g., frontal headache, epiphora, blurring of vision, burning, itching and smarting of the lids. No small number of these, upon a careful subjective examination, will be found to have normal vision for distance. When such is the case and the patients are refracted under a mydriatic (1 per cent atropin sulphate solution instilled into the eye three times a day for three days) many will show through retinoscopy but the smallest degree of refractive error. Neither will there be a muscular imbalance. It is plainly evident that the findings are out of all proportion to the ocular symptoms from which they complain. In most instances the cause lies in faulty hygiene, poor housing, poor or insufficient food or lack of sleep. If, in such cases, glasses are prescribed, they will be worn for a time through compulsion, novelty or imitation and will finally be cast aside. Some of these little patients are underweight and anemic,

*Presented before the annual meeting of the Minnesota State Medical Association, St. Paul, October, 1923.

others scrofulous with hypertrophied tonsils and adenoids, enlarged cervical glands, follicular conjunctivitis, eczema, et cetera. The course of treatment to be pursued is self-evident.

Migraine headaches can usually be differentiated from those resulting from eye strain if sufficient history be taken. This malady affects women more frequently than men, in a proportion of about three to one. There is a marked hereditary tendency. In women it has its onset about the age of puberty and usually continues until after the menopause, pursuing its course in the form of paroxysmal attacks at regular intervals. Such is the general rule which finds many exceptions. The attacks may occur weekly, fortnightly or monthly and are very commonly present at the time of menstruation. Generally, the headache at first involves but one side of the head, usually the forehead or occiput, gradually extending over the whole calvarium. The pain is of a throbbing or binding nature and may be accompanied by sparkling light before the eyes which increases in extent until finally the patient is temporarily blind (scintillating scotoma). During these attacks the patient may complain that he sees only a portion of an object, the right or left, upper or lower half (hemianopia). Dizziness, nausea and vomiting are commonly present. Such a seizure lasts usually from six to twelve hours, sometimes longer, even for two or three days.

All gradations of the above clinical picture may occur. It is usually the atypical case who consults the oculist, with the hope that by a proper fitting of glasses headaches will cease. If, in such a case, the headache displays a hereditary tendency and periodicity over a considerable length of time and without particular reference to the use of the eyes for close work, the condition can be stamped as migraine. Minor errors of refraction should be corrected and in a few cases will prove helpful. That such a remedial measure will abolish an attack of migraine would be asking too much.

A condition allied to migraine headache is that associated with nervous asthenopia (copiopia hysterica). The condition differs from migraine in that the symptoms are a daily occurrence and are not subject to periodic attacks. Reading, even for a very short period of time, so fatigues accommodation that headache and blurred vision result and work must be set aside. Usually, it is only upon using the eyes for close work that the ocular symptoms become manifest. There are cases, however,

in which the headache begins in the morning upon rising and is aggravated by reading. There may even be a sensitiveness of the eyes to light. Nervous asthenopia is frequently a symptom in women during the menopause. A diagnosis of nervous asthenopia can only be made in the absence of a refractive error or muscular imbalance proportionate to the degree of ocular symptoms present. Correction of minor errors of refraction will prove of no benefit in this condition.

Quite commonly hysterical and neurasthenic patients refer their headache to eye strain. As clinical entities, these conditions are so closely allied from an ophthalmological standpoint, that their symptomatology may be spoken of collectively. All gradations and combinations of the following ocular phenomena may be present; headache, muscular imbalance, poor visual memory, limitation of the visual field, imperfect accommodation, drooping of the lids, irregular or hyperactive pupils, temporary obscuration of vision, optical hallucinations, limitation of the color and light sense. While it is true that the exhaustion field is characteristic for neurasthenia, it sometimes occurs in hysteria. In this class of cases, the headache is more a sense of pressure, weight or fullness and, while it may be frontal or occipital in location, is frequently referred to the vertex. Tenderness of the scalp is not uncommonly associated with it. Optical correction of existing minor errors of refraction or measures for the relief of low degrees of muscular imbalance may prove helpful, but are rarely adequate.

An affection not infrequently mistaken for headache of ocular origin is the so-called vacuum headache, a condition established as a clinical entity by Sluder* and Ewing.* This malady is described by Sluder as "a low grade unending headache" brought about through the closure of the frontal sinus without nasal symptoms or signs (e. g. obstruction or secretion) and made worse by use of the eyes. The pain experienced is due to a partial absorption of the air contained within the sinus, with a resulting negative pressure rendering the walls sensitive. The headache though frontal is occasionally referred to the external angular process of the frontal bone. This type of headache is characteristically present in the morning, becoming worse with the use of the eyes for near work. However, there are cases where headaches are only precipitated by the use of the

*Trans. Am. Ophth. Soc., 1900.

eyes for near work. Unlike headaches due to eye strain, and which are generally a daily occurrence, vacuum headaches characteristically appear at irregular intervals and may disappear as suddenly as they appear. Just as in empyema of the frontal sinus, this type of headache is increased on stooping and often attended by a sense of dizziness. Ewing's sign, "tenderness of the upper, inner angle of the orbit at the point of attachment of the pulley of the superior oblique muscle and internal and external to it" is pathognomonic of the condition. As the function of this muscle is to turn the eye downward and inward, it is called into play during the act of accommodation, necessitating a tugging at the tender point. The tenderness of this area is explained by Sluder "as arising from a closure of the outlet of the frontal sinus thereby producing a negative pressure through absorption of the oxygen therein contained with a resulting congestion of the lining membrane together with the underlying bone." Tenderness of the eyeball to backward pressure, a clinical sign to which but little attention has been given, is almost always present. The nasal conditions that may give rise to vacuum headache Sluder groups into the following classes: (1) when there exists an enlargement or tilting of the septum tubercle out of the midline in a normal or particularly narrow nose; (2) narrowing or occlusion of the hiatus semilunaris through anatomical variation so that the uncinate process and bulla are in contact; (3) edema of the vault of the middle meatus; (4) anatomical insufficiency of the vault; (5) middle turbinate hypertrophy; (6) empyemas or coryzas that have gotten well but have left a degree of swelling in the vault of the middle meatus sufficient to keep the frontal sinus closed.

In view of the fact that this malady has a nasal origin, generally without a demonstrable gross anatomical or pathological change, it is difficult at times to convince oneself that this is the proper diagnosis in a given case even when there is present Ewing's sign, a tender eyeball and a history of periodic attacks. Fortunately, vacuum headaches lend themselves readily to a reliable therapeutic test. If a patient appears during an attack of headache it is the writer's custom for diagnostic purpose to place a pledget saturated with 1-1,000 adrenalin or an astringent beneath the middle turbinate for a few moments. If after a short time the headache disappears, or is diminished in its

intensity, it is strong presumptive evidence that this symptom is due to insufficiency or lack of aeration of the frontal sinus. Treatment consists of applications of astringents to the region of the nasofrontal duct and when this appears inefficient or inappropriate, surgical procedure for the purpose of removing pathological or purely obstructive tissues.

From a differential diagnostic standpoint headaches due to eye strain will not be contrasted with those arising from empyemas or hyperplastic conditions of the paranasal sinuses. It is enough to say that so intimate is the anatomical relationship between the eyeball and the accessory sinuses that an examination of the former should be accompanied by a routine examination of the latter. If this is carried out, usually enough pathological evidence will be found within the nose to stamp a headache arising from this source.

Neuralgic phenomena, the expression of nasal (sphenopalatine) neurosis, offer a symptom complex too involving to be confounded with pain associated with eye strain.

The types of headaches ordinarily mistaken for those arising from eye strain have now been mentioned. To elaborate further would only prolong the paper to undue length. Speaking in general it is imperative for the proper estimation of optical error that the patient be refracted under a mydriatic, atropine in children, homatropine in the adult. It should ever be kept in mind that the retinoscopic finding, in the final analysis, is but a guide, the trial case the court of last appeal. A good refractionist is one possessing the following requisites: knowledge, accuracy, experience, judgment. Minor errors of refraction, those within physiological limits which apparently give rise to eye strain, should be fully corrected. But before this remedial measure is applied the case should be studied from a differential diagnostic standpoint. Is the headache really due to eye strain?

DISCUSSION

DR. JOHN FULTON, Saint Paul: I have had the privilege and pleasure of working with Dr. Berrisford for the past four years at the Saint Paul Free Dispensary, and I am familiar with the painstaking care and the absolute accuracy with which the refractive work is done. I read his paper a few days ago. He has added many important points to it since. Dr. Berrisford has given us a very excellent presentation of this very important branch of ophthalmology.

The percentage of eye cases coming before us suffering with headaches on account of eye difficulties is variously

estimated by different authors. Hogue, of Milwaukee, affirms that 50 per cent of headaches are due to eye strain. De Schweinitz, one of our most conservative and best known oculists, estimates that 70 per cent of all functional headaches are caused by eye strain.

The best definition of ocular headache that has been given is as follows: "An acute discomfort in and about the head that directly or indirectly results from organic or functional disorder of the visual apparatus."

The pain is usually frontal or occipital, but it may radiate to many other places: between the shoulders, in the precordia and deep in the mastoid.

The degree of refractive error has nothing to do with the amount of discomfort produced. In fact, the lower degrees seem to produce the most trouble. The same remark also applies to muscular insufficiencies.

So when the question is asked, what degree of ocular or muscular trouble should be corrected, my answer is: any degree that gives rise to severe symptoms that interferes with the patient's work and cannot be relieved by local and constitutional remedies.

The author of the paper has referred to migraine. I agree with Wilder in saying that this trouble is not of ocular origin, but seems to bear a relationship with the function of the pituitary body. Some of the best known English oculists claim that they have given great relief to the unfortunate persons who suffer from this malady by the internal administration of the whole of the pituitary gland as prepared by Armour.

The question naturally arises, how does eye strain produce headache? I heartily agree with Dunn and Ellis in thinking it is produced by increase of intracranial pressure. In a recent paper published by Dunn in the Archives of Ophthalmology, March, 1918, he enters into a prolonged explanation as to how this pressure is produced, but on account of the brief time allotted to us, it cannot be entered into here.

Jackson has called our attention to a class of patients suffering from pulmonary tuberculosis with lesion of considerable extent, but with great systemic resistance, who suffer with the most annoying asthenopia and ocular headaches, the correction of which gives the patient **marked** relief, but never complete until the lung trouble is completely healed. In many of these cases they are able to discard the glasses after complete convalescence from the tuberculous trouble.

The moving pictures are often accused of producing severe eye symptoms and headache. I am convinced that this never takes place to normal eyes. In fact, I am in the habit of telling my patients, after they have been refracted, to go and try the movies, and if they find their eyes are perfectly comfortable, I know their refractive trouble has been properly corrected.

A form of asthenopia, which is much neglected and too frequently looked upon as hysteria, is retinal asthenopia. In other words, this is an irritable retina. All bright lights are very annoying to the patient; they have distressing after-images and various kinds of color scotomata. Very great relief can be obtained for this trouble by the liberal use of adrenalin, both before and after refractive and muscular correction. Ocular headaches are due to fatigue. The most common exciting cause is long, continued use of accommodation and convergence in near work. The underlying ocular condition that brings this about is hyperopic astigmatism, associated with heterophoria.

The instinctive desire of everyone having refractive and muscular errors to maintain single binocular vision and normal clearness of sight is also a great factor in producing headache. People with one eye or those with one eye so defective that fusion of images is impossible, rarely have this form of trouble.

DR. JOHN FULTON, Saint Paul: I see we have Dr. Collins here from Duluth, one of the oldest and most experienced oculists. I think we would all like to hear from him.

DR. HOMER COLLINS, Duluth: I want to say that my experience has been in exact accord with Dr. Berrisford's, and I think he has covered the subject thoroughly. I really have nothing to add. The vacuum headaches we do come across occasionally, and often—as Dr. Berrisford says—they are more apt to be confusing because the nose shows so little abnormality. The only way I have ever found for testing was exactly the method he has used, shrinking the nasal mucous membrane, and then the relief was almost instantaneous.

DR. BERRISFORD, St. Paul (closing): I wish to express to Dr. Fulton my sincere gratitude for the prominence he has given my paper by discussing it. His well known skill and wealth of experience gives to his remarks the utmost importance.

One portion of the paper I wish especially to emphasize: "vacuum headache" is a clear-cut and distinct clinical entity. It is difficult, at times, to convince oneself that this ailment is of nasal origin in view of the fact that upon rhinological examination the nose shows little if anything that might account for the symptoms manifested. However, the presence of a tender eyeball, tenderness at the upper inner angle of the orbit described by Ewing, and a history of periodic attacks are facts which very strongly suggest this diagnosis. If, during such an attack symptoms are rendered less severe or wholly disappear as the result of the therapeutic test already described, a diagnosis of "vacuum headache," the result of improper aeration of the frontal sinus, is justifiable.

BRONCHIAL ASTHMA*

JOHN M. LAJOIE, M.D.
Minneapolis

Asthma is a term which has been more or less loosely applied to conditions having dyspnea as a pronounced symptom. What has been learned during the past decade points to hypersensitiveness as the basic cause of asthma, so we shall restrict ourselves to bronchial asthma—a condition resulting from allergic reaction.

The vast amount of work done in the past ten years has done much to place the treatment of this disease on a satisfactory basis and permit it to be classed as a curable disease. Nothing new is being offered at this time because what is needed is a better comprehension of the facts already known, instead of piling up more. We are crushed and suffocated with dry, single facts. I agree with Van Rijnbert, the editor of *Tijdschrift*, who says, "What a blessing it would be if all the journals of the world would agree not to publish any new facts for ten years and devote their pages to collective reviews and monographs on the facts already known."

After being successful in treating a few cases of bronchial asthma, I felt very proud of my knowledge, but as the number of patients I saw increased, my pride decreased and now I am very humble.

A neurotic family history, epilepsy, hysteria, hay-fever and eczema are frequently connected with bronchial asthma. Anaphylaxis is especially apt to occur.

Asthma commonly commences during the first decade, but may begin at any age. Unless relieved, it persists to old age.

The exciting causes of a paroxysm are of great variety. Conditions of climate and atmosphere; emanations from leaves, flowers or animals; various dusts; food proteins; bacterial products; chemical substances, nasal polypi and emotions and nervous disturbances are some of them. What may be a cause today may not be a cause at a later date. A complicating bronchitis may become a cause. Since there are such a large number of causes of asthma it is frequently, and at times impossible, to detect the cause.

The mode of onset of asthma, or the symptoms preceding the initial attack of asthma, has little bearing upon the cause, since, in the majority of

cases, the onset is preceded with what the patient calls "a cold" or "bronchitis."

The time of year in which an attack of asthma begins and the season of the year, if it always limits the attack of asthma, are important. Attacks during the summer months are usually caused by the protein in the pollen of plants. In many instances this summer type of pollen asthma is prolonged throughout the year by bacteria. In those who have had asthma for a considerable length of time there may be bronchitis and emphysema, so that the removal of the offending cause must be followed by treatment of the bronchitis, if we are to get relief.

When a person is sensitive to a specific substance certain symptoms are produced by that substance when taken into the body. Proteins are widely distributed in nature and it is the protein in the substance which causes asthma. Proteins enter the body by ingestion, as in foods; by inhalation, as in pollens, dust and dander; by absorption through the skin and mucous membranes; by infection, from pathologic bacteria in teeth, tonsils, nose, throat and lungs; and by injection with horse serum. In the case of bacteria we have to deal with the protein element as it is the protein element only which makes a positive skin test. A negative test does not rule out a particular bacterium as a cause, since the infectious element of the bacteria may cause the asthma.

The attacks are frequently during the night, after a few hours of sleep. The onset is fairly sudden with premonitory symptoms of oppression in the chest and may be accompanied by sneezing, flatulence, polyuria and great depression. During the paroxysm the respirations are slow with short inspirations and long, wheezy expirations. There are strong contractions of the accessory respiratory muscles. The patient is pale or cyanotic and anxious. There is cold perspiration on the skin. There may be paroxysms of coughing until a viscid sputum is raised. Then relief follows. An attack may last from a few minutes to a few hours. The patient sits, leaning forward, and may grip something to reinforce the chest muscles. The thorax is fixed in the expanded position. On percussion there is hyperresonance and on auscultation numerous musical râles and noises may be heard.

The sputum contains small gelatinous masses, being spirally twisted casts of the small bronchi. Often numerous eosinophiles are embedded in

*Presented before the annual meeting of the Minnesota State Medical Association, St. Paul, October, 1923.

them. These masses, or "Curschmann's Spirals," are quite diagnostic of true asthma, but are usually absent in old cases with emphysema. An eosinophilia of from 5 to 30 per cent may be present in the blood. Only in bronchial asthma do a blood and sputa eosinophilia occur simultaneously. Eosinophilia is regarded as one of the chief clinical and pathologic symptoms of allergy.

When there have been several severe and prolonged attacks, more or less emphysema develops. One would expect some cardiac hypertrophy in cases of long standing, but hypertrophy is not always present.

Huber and Koessler,¹ in their microscopic study of the lungs of sixteen cases of the bacterial type of bronchial asthma, found hypertrophy of the bronchial musculature (4 cases); cellular infiltration (3); eosinophiles (3); thickened bronchial arteries (2); extensive cellular infiltration of the bronchial mucous glands (2); atrophy of the bronchial glands (1); calcified and ossified bronchial cartilages (2); occlusion of bronchioles (2).

In making a study of a patient having symptoms of asthma we follow a definite routine as far as it is practicable or possible. The routine is followed both in private practice and at the Minneapolis General Hospital. This is of necessity if we are not to overlook some important finding. Besides, it is good practice.

1. A complete history is taken and recorded, giving special attention to age at onset of symptoms; seasons when symptoms begin or are worse; place where attack began; what makes it worse; what gives relief; whether occupation is a factor and all circumstances associated with the first attack.

2. Complete physical examination, including a diligent search for foci of infection.

3. Examination of sputum and nasal secretions.

4. Complete blood examination.

5. Wassermann of the blood.

6. Urinalysis (24-hour specimen).

7. Basal metabolism estimation.

8. Skin tests to the proteins in food, pollen, animal hair and dander, bacteria, et cetera.

9. Roentgen ray of lungs, heart, paranasal sinuses and teeth.

10. Nose and throat examination.

11. Complete dental examination.

12. Tuberculin test.

13. Other special examinations when indicated.

SENSITIZATION

The subject of sensitization is relatively new and comparatively few realize its importance and the amount of study that it has received in the past few years. Various terms are used to express sensitization. The commoner ones are "hypersensitiveness," "allergy," and "anaphylaxis." Anaphylaxis was discovered in 1902 by Richet. He called it "anaphylaxis" because he incorrectly thought it was opposed to "prophylaxis." Eight years later Meltzer noted the similarity of the bronchial obstruction of asthma and that found in animals dying in anaphylactic shock.

Active Sensitization.—As far as we know, sensitization is caused by the protein element in a substance. Proteins are widely distributed in nature and are present sometimes where we least expect to find them. As they concern us, they are present in food, animal dander and hair, house dust, bacteria, pollens, face powders, sachets and drugs.

We are beginning to recognize that there are different kinds of sensitization. Pinness² observes that anaphylaxis is an induced and experimental hypersensitiveness in animals; it is rare in human beings; while allergy is a natural, inherited hypersensitiveness affecting only human beings. The hypersensitive state may be present at birth, inherited or conveyed by mother to child.

The body cells produce specific antibodies following the injection of protein. After a certain time antibodies are produced in such quantities that, upon re-introduction of the same protein, certain symptoms follow. These symptoms are generally called "anaphylactic shock."

Example.—If you inject a guinea pig with 1 c.c. of horse serum, no symptoms are observed. If you inject .01 c.c. of serum daily for twelve days and then inject 1 c.c., no symptoms are produced. If you wait twelve months and then inject 1 c.c. of serum, you will get anaphylactic death. (The pig was previously immunized and has returned to the sensitive state.) If you inject a guinea pig with .01 c.c. of serum and in fifteen days inject 1 c.c. of the same serum you will get anaphylactic death. If you inject .01 c.c. of serum and in twelve days inject a sublethal dose you may get symptoms, but not death; then you may give several c.c. of serum without symptoms. The sublethal dose has, for the time being, desensitized the animal. It has united with the antibodies and taken them away from the cells. The antibodies are not now attached

to the cells. After a time the antibodies will become attached to the cells and then the union of antigen (protein) to them will produce symptoms. A guinea pig may be sensitized by an amount as small as 0.000001 c.c. of serum.

When antibodies are few and attached to the cells we have the sensitized state. When they are in excess we have the immune state.

In the guinea pig death results from the contraction of the smooth muscles in the bronchi.

Passive Sensitization.—If you take serum from an animal that has been actively sensitized and inject it into a normal animal and wait for two days you will find that the second animal is sensitized to the same protein as was used to desensitize the first animal. This transfer of immune bodies from one animal to another, by means of serum, is an example of passive sensitization.

It is possible to sensitize human beings in this artificial way to a foreign protein, but, unlike the guinea pig, they do not of necessity remain permanently sensitized. In a number of clinical conditions sensitization has occurred, not through any known artificial way, but in an unknown natural way. In this group are hay-fever, bronchial asthma, angioneurotic edema, and acute gastro-enteritis. These are examples of allergy.

When a definite type of cells are sensitized we get a group of symptoms depending upon the character of the cells. If the smooth muscle fibers in the bronchi are sensitized, together with the mucous membrane cells in the bronchial tree, we have the symptoms of bronchial asthma. When the mucous membrane of the eye, nose and throat is sensitized, we have the symptoms of hay-fever; when the cells of the gastro-intestinal tract are sensitized, we have gastro-enteritis; when of the skin, we have urticaria, and when of the connective tissue, we have angioneurotic edema.

Coca gives the following differences between anaphylaxis and allergy:

1. The exciting agent of anaphylaxis is always antigenic in character. The exciting agent of allergy may or may not be an antigenic substance. (For example: it may be a drug such as arsphenamin or acetylsalicylic acid.)
2. Although anaphylaxis may be transmitted from mother to offspring, it is not inheritable in the true sense of the word. It is always, primarily, an artificial condition induced by

the introduction of antigenic substance into the body of some susceptible animal.

Allergy, on the other hand, is always based, primarily, on a natural inherited makeup. The sensitiveness classed as allergy does not in every instance appear to depend on previous contact with an exciting substance. An individual, for example, may have a violent allergic reaction when he comes in contact with the exciting substance apparently for the first time.

3. The phenomenon of desensitization, which can quickly and invariably be brought about in animals with anaphylactic sensitiveness, is entirely wanting in allergy. The state of reduced sensitiveness observed clinically, after treatment of allergy by hypodermic injections of the exciting agent, is never complete nor is it comparable with the above.

Human beings who have become sensitive to some protein are far more sensitive than animals that have been sensitized by injecting foreign protein. For example: It takes relatively more foreign protein with animals, which have been sensitized, to produce marked symptoms than is required in a sensitive human being.

The time of the occurrence of symptoms varies in human beings. It varies from a few seconds to several hours. A patient may be sensitive to a protein at one time and only mildly sensitive a week later, or he may not be sensitive at all. It has been shown that, when an animal is sensitized to three antigens, desensitization to all three might be effected by using only one of the antigens.

The important clinical manifestations of sensitization are: (1) allergy and anaphylaxis; (2) the immune reaction to smallpox vaccine; (3) the tuberculin reaction; and (4) serum sickness.

In serum sickness the symptoms appear from the first to the fifteenth day after injection. The symptoms are late after an initial injection, but after a second injection they usually occur in from three to six days with more marked local and general reaction, and edema and urticaria may be present in twenty-four hours. A reaction consists of a rash which is very itchy and may be accompanied by painful swollen joints, adenitis, albuminuria and fever.

THE SKIN TEST

One of the most practical ways of discerning whether a patient is sensitive or not is by means

of the skin test. Von Pirquet's test with tuberculin "O.T." is the basis for all tests of this kind. A positive reaction consists of a distinct urticarial wheal surrounded by a zone of erythema in the presence of a negative control test. A true reaction is always indicated by a wheal having an irregular outline.

The skin test should not be relied upon entirely, and its results should be used only as a clue. I will mention some of the reasons for this statement. There are occasional transitory periods during which a patient may not react cutaneously to a protein to which he is sensitive. This makes it necessary to make repeated tests in suspected cases. About 50 per cent of the people who are sensitized at all show multiple sensitization and a patient, at the time of the test, may be temporarily desensitized to one or more of the proteins being used and will be cutaneously negative to that protein, although he reacts positively to some other protein. One should not allow a negative skin reaction to rule out a protein which is strongly suspected. One may also get a positive reaction, due to the fact that the cutaneous cells are sensitized, even though they are not involved directly in the clinical type of the disease.

Besides testing with proteins from the usual foods, pollens and animal emanations, one frequently must suspect unusual sources of protein such as street dust, house dust (including that from wall paper), wall hangings, glue, boxwood, face and tooth powders, woolen and grass rugs, pillows, mattresses, felt hats and many others. When the skin tests fail to give any definite information it may be necessary to try some of the suspected substances on the patient, always remembering that ingested food or inhaled dust may not produce symptoms until six or eight hours have elapsed.

ASTHMA IN CHILDREN

Ratner³ calls our attention to the fact that many physicians still labor under the impression that very young infants do not suffer from asthma. He states that recurrent attacks of hypernea or dyspnea, without a rise in temperature and with the lungs containing sibilant and sonorous râles which gradually clear up in twenty-four to seventy-two hours, should be looked upon as asthma, no matter how young the infant; and that the cessation of râles, after the injection of adrenalin or atropin, will prove the diagnosis.

Abt⁴ states that, clinically, we may recognize two main varieties: (1) cases associated with bronchitis, and (2) cases characterized by sudden onset with a tendency to periodic recurrences. The first form begins with marked bronchitis, fever, lassitude, rhinitis, restlessness and even delirium. Anorexia and vomiting may occur. Respirations may be fifty or eighty per minute. The breathing is loud and noisy. There is an immobile appearance of the chest during expiration. Numerous dry, whistling, sibilant râles are heard. The cough is disturbing. The second type of asthma, as it occurs in children, resembles in many respects the asthma of adults. As a rule, children who have apparently been in normal health are suddenly attacked with severe dyspnea shortly after retiring. The chief trouble is expiratory. The lungs are hyperresonant. Loud, whistling and sibilant râles are heard. The attack usually disappears suddenly.

We must be careful to differentiate asthma from diphtheria, acute laryngitis, whooping cough, retropharyngeal abscess, enlarged bronchial glands, enlarged thymus, congenital stridor, foreign bodies in larynx or trachea and ulcer of the larynx.

The common sources of foreign protein in infants' food are milk and egg. Shannon and O'Keefe have shown that infants may be sensitized to foreign protein by the passage of these proteins through the mother's milk; while Hermann has reported that pollens may pass through cows' milk and that individuals, who are sensitive to pollen, will have symptoms on taking this milk. It is frequently observed that a case sensitive to egg will get no reaction if the egg has been well cooked, and that a case sensitive to milk will frequently be able to take boiled milk without symptoms.

TREATMENT

The treatment of asthma is the treatment of the cause. A careful history is the most important part of the study to bring out the cause. Each patient with asthma presents a definite problem for solution. Practically no two cases are alike, and this fact makes it difficult to give any classification of treatment and, perhaps, explains why one form of treatment gives results in one case and not in another having, apparently, the same cause.

First, all foci of infection should be properly treated, as some patients have an attack of asthma as a result of a focus of infection rather than an arthritis or an attack of neuralgia. A few cases have been reported where the patients had an at-

tack of fever of obscure origin followed by an improvement in their asthmatic condition. This suggests that the successful treatment of asthma may, in certain cases, be sought in the factors causing or associated with fever.

I saw a patient three years ago suffering from very severe asthma. Before any relief was obtained she went to Florida and then to California and, after getting the advice of several physicians and trying various remedies, finally came home in disgust. A short time after her return home her asthma suddenly left her and she has had complete freedom for over two years. This appears to be a spontaneous cure.

If the food group of proteins is the cause, the foods containing them should be completely avoided for at least four or five months. If this is impracticable, the patient should be desensitized against the offending protein. Desensitization, unfortunately, lasts only a few months.

If asthma is due to the pollen group, the patient should receive subcutaneous injections of pollen antigen beginning fourteen weeks prior to the expected date of attack.

If asthma is due to epidermal dust or to hair, the patient may be desensitized, but it is better to keep him away from the source of the offending substance.

If asthma is due to orris root or drugs, these should be avoided. If due to house dust, desensitization or a change of climate would be indicated. As a general rule some benefit may be obtained by some supervision of the patient's mode of living. The diet should be low in animal protein, patient should have a short period in bed to improve the digestion, and a change of climate may be of value. Discipline is essential, as many asthmatics have strong neurotic tendencies.

Good results have been reported in a few instances by the use of non-specific proteins such as typhoid vaccine, defibrinated blood from the patient and also injections of peptone. Many asthmatics show a great sensitivity to tuberculin. Tuberculin, in many instances, exerts a beneficial effect upon them. Tuberculin therapy should be cautiously tried where a specific agent, coming from without, cannot be determined. Tuberculin therapy may be of use as an auxiliary to specific protein therapy. Give 1 c.c. of a 1 to 100000 dilution of Koch's O.T. on alternate days. Increase dose after

a few days, but avoid reactions. Too large a dose may cause a severe attack of asthma.

A certain number of patients have a chronic bronchitis accompanying the asthma. In these cases treatment of the bronchitis should be added to whatever other treatment they are receiving. A vaccine made from the predominating organisms in the sputum offers very good results in about 50 per cent of these so-called bacterial asthmatics. To get the best results in this type, the vaccine must be made by a competent serologist and administered by one who understands vaccine therapy. The permanency of relief depends upon the amount of treatment and the patient's power of resistance. Vaccines are successful only in case some local reaction at the place of injection follows the subcutaneous dose. The usual initial dose is 100 million, rapidly increased every fifth or sixth day until local reaction occurs, or until five or six injections have been given without local reaction. Vaccines produce only active immunity. They should be used with great care in the presence of acute infection. Their greatest use is in the recurrent type of asthma where, by producing a degree of active immunity, the hope of modifying the next attack is reasonable.

The following cases are reported because of the apparent specific action of the vaccine used.

CASE REPORTS

No. 8213 (M). Widow, aged 60. Always quite well until September, 1920, when she developed bronchitis and asthma. In bed thirteen weeks. In January, 1921, her physician did an extensive nasal operation, thinking it would help the asthma. Asthma and cough disappeared two days after the operation, but returned in five weeks. On Feb. 1, 1921, she had a second nasal operation without any good effects, and asthma continued. She consulted me in August, 1921, asking for enough relief so that she might get along without a nurse. She had difficult breathing in attacks lasting from one to several hours at a time, worse at night. There was a productive cough; circulatory, digestive and urinary systems appeared normal. Tonsils and all doubtful teeth were removed six months previously. Lungs were slightly emphysematous, with prolonged expiratory murmurs, accompanied by numerous and various types of musical râles. She was negative to various skin tests. A vaccine obtained from her sputum was given her and at the end of three weeks she was completely relieved. One month later she sat for a half hour with her feet in cold plaster of paris and two days later she was having severe bronchitis and asthma, with a temperature of 102. A vaccine was prepared and given her and she again had complete relief. Again, on Jan. 1, 1922, she rode in a cold street car and soon had severe bronchial asthma, which was cleared up after six injections of autogenous vaccine. She is at present having no difficulty.

No. 8076 (G). Previous history negative. On Sept. 26, 1920, patient developed a severe attack of urticaria, two days after eating barracuda (deep-sea fish). Since then red meats, ice cream or chocolate aggravate the urticaria. On examination, all organs appeared normal. Skin had some large areas of urticaria. Complete blood examinations, including Wassermann, were normal. Roentgen ray of the gastro-intestinal tract showed ileo-stasis, otherwise negative. The urine was negative. One year later she developed bronchitis with difficult breathing, followed in two days by urticaria and numerous musical râles in both lungs. The usual skin tests were negative, except for the streptococcus hemolyticus, non-hemolyticus and viridans, which were slightly positive. An autogenous vaccine was made from the sputum. One c.c. of a vaccine containing streptococcus 50 M to c.c. and gram positive diplococcus 200 M to c.c. was given, and two days later she had a severe attack of urticaria. Then she was given 0.00005 of a c.c. and, two days later, had slight urticaria, and on trying different dilutions it was found that 0.0000001 c.c. did not produce urticaria. This was increased to 0.00005 c.c. without urticaria. Then she developed sudden rise of temperature to 104 and general aching, with some soreness in the breast, followed, in twenty-four hours, by the worst attack of urticaria she had ever had. These symptoms subsided in about three days and returned in two weeks, with similar results. There did not seem to be fluctuation in the breast but, because of the history, it was opened about ten days later and two ounces of pus obtained. A culture from this pus gave a pure growth of large gram plus diplococcus, the same as was found in the sputum. The patient has had no asthma or urticaria for the past two years.

CONCLUSIONS

A careful history often gives the clue to a correct diagnosis. Such a history, a complete physical examination, and properly interpreted skin tests, are the three essentials in the diagnosis.

Bronchial asthma may have widely different etiologic factors. It is frequently a complication of, or augmented by, pathologic agents.

The symptoms in infants may be unlike those in adults.

Asthma may now be regarded as a curable disease.

The treatment may vary greatly in different individuals. It depends entirely upon the cause of the asthma.

DISCUSSION

DR. C. N. HENSEL, St. Paul: The fundamental principles underlying the diagnosis and the treatment of bronchial asthma on the basis of protein sensitization, are pretty well established. These principles have been adequately presented by Dr. Lajoie and so, in discussing his paper, we need only emphasize certain points. First protein sensitization is not a cure-all, but is a means by which we can make differential diagnoses in cases of bronchial asthma, between the conditions in which the patient is sensitive to foreign proteins causing his asthma, and conditions in which he is not sensitive.

We must recognize that the skin tests are absolutely specific, and if we are guided by the skin tests we have an index to treatment. We must remember that in cases of asthma coming on in the early years of life, even up to thirty-five years of age, in a large proportion of the cases (upwards of ninety per cent), foreign proteins are the cause. You get a positive skin test, and following along the lines of that positive skin test you get relief in treatment. From thirty-five to forty-five years you have a larger proportion of cases that are not sensitive. In cases beginning with bronchial asthma after forty-five very few show positive skin tests, and therefore the specific line of treatment is not indicated.

If we bear these two facts in mind, namely, that the cases with onset in early life are the protein positive cases and the cases with onset in later life are the protein negative cases, then we have two general guides for treatment. In the young the foods play a prominent part, animal emanations another prominent part, plant pollens causing less disturbance. In older people the conditions are much more likely to be cardio-renal disease, associated with hypertension and chronic sinus disease. I personally have had very little success in the removal of tonsils in these cases of asthma in middle life, but I have found a great deal of success in having these cases examined by a careful nose and throat specialist with reference to the middle and superior turbinates and with reference to ethmoid infection and nasal polypus.

The case that Dr. Lajoie described apparently has a sinus infection of low grade. Perhaps pus is not directly demonstrable, but there is a stringy, glairy, viscid mucus. Those cases light up asthma due to any chilling as the doctor has described. These are the cases where adequate nasal treatment relieving nasal pressure give a great deal of relief.

And finally, in the adult non-sensitive type of cases, as Dr. Lajoie has said, autogenous vaccines are found helpful. Sometimes your laboratory will report two organisms which show equal growth. Vaccines should be made of both strains, testing the patient with both, and using the strain finally which gives you the local reaction at the site of the inoculation.

In conclusion, do not denounce the skin test because you do not always get a positive reaction.

You cannot expect positive reactions in more than 60 per cent of all your cases, certainly a sufficient percentage to make it worth while.

DR. C. B. WRIGHT, Minneapolis: I feel, with Dr. Lajoie, very humble in discussing this subject because my personal experiences have not been so brilliant as the literature which I have read. There are a number of things, I think, in the discussion of this subject which are of great interest. First, one will, of course, be successful in the treatment of these cases in direct proportion to the amount of thoroughness and care with which he studies each individual case. Since the use of the desensitization test I think there has been somewhat of a tendency on the part of men working on this subject not to study as carefully as they should the clinical findings on the patient himself and to assume that because he is sensitive to certain proteins he must have true bronchial asthma and on that basis one is, of course, apt to fail.

In order to prove, it seems to me, that the offending protein is the cause of this disease, one should not only be able to get sensitization of the skin but he should also be able to cure the patient by the removal of this protein. Without that therapeutic test I think our conclusions are entirely groundless. The greatest difficulty we have in the differential diagnosis of asthma is with the older patients. In cases that start in patients over fifty years of age it is usually not true bronchial asthma but it is chronic bronchitis.

This is the field in which the proprietary medicine has officiated for years, and I believe we have a remedy made in St. Paul on the basis of our good friends, stramonium leaves and saltpeter, and it is a very valuable thing in relieving acute attacks. In addition to that, the other antispasmodics are used in this type of case. The very old patients present a difficult proposition. Once in a while a vaccine will do them some good, but my experience is not so entirely satisfactory as the literature would lead me to believe.

The whole subject is a large one. Then there are so many ramifications, so many different types of cases that later get attacks of dyspnea or asthmatic attacks that the whole situation depends, first, in my opinion, on the thoroughness with which these cases are worked up and, secondly, on the co-operation of your patient; that, in my opinion, is the most difficult thing of all. In the young, where our results should appear most favorable, if we get these cases they are the most difficult people to co-operate with. They come in for immediate relief and you only see them again when they come back for relief again. The older patient will always co-operate but unfortunately that is the type of case in which we get very much less brilliant results.

DR. JOHN M. LAJOIE (closing): I have nothing further to add except to bring to your attention a few points. We always try to get the co-operation of the patient and make a thorough physical examination in an attempt to locate any foci of infection and, if the patient is under forty-five or fifty, make thorough skin tests with various proteins. It sometimes happens that an asthmatic consults a physician and, because he has asthma, nothing much is done for him. A prescription will probably be given him with the hope that it may help him. I have seen a few patients who have had this kind of treatment. I believe that with good, hard work, coupled with a vivid imagination, we will be more successful in the future than we have ever been in the past in discovering the cause of bronchial asthma in a given case.

DON'T WORRY IF YOU CAN'T SLEEP NIGHTS

To make a business of sleep is a bad habit. That is what persons do who worry because they can't sleep.

In answering a question about insomnia, *HYGEIA*, the popular health magazine, in its April issue declares that the chief harmful effects from not sleeping are caused not by sleeplessness, but by worry over not sleeping.

Sleep should and will come naturally, if one will only realize that it is rest and not sleep that is needed, says the health journal.

Of course it is important to pay attention to the ordinary

rules of hygiene, with regard to exercise, fresh air and reasonable diet. But, above all, it is important to fill one's life with satisfactory work and play.

The best incentive to sleep is still the feeling of "something attempted, something done," particularly something to help others.

As to the amount of sleep needed by different persons, that varies within wide limits and is much modified by habit. Many energetic, active individuals get along quite well with four or five hours of sleep. The proper amount for the average adult, however, is usually between seven and eight hours.

DIAGNOSIS OF ANOMALOUS RENAL ARTERY AS A CAUSE OF UPPER URINARY TRACT STASIS*

FREDERIC E. B. FOLEY, M.D.

Urologist, Miller Hospital Clinic

St. Paul

Anomalies of the renal circulation are of common occurrence. They are found as abnormal divisions or distributions of an otherwise normal artery given off from the aorta or, as is more important in the present connection, as supernumerary trunks from the aorta. Such an abnormally placed division of the renal artery or anomalous supernumerary trunk may lie in sufficiently intimate contact with the upper ureter or uretero-pelvic junction to interfere with the peristaltic expulsion of urine from the renal pelvis.

The earliest mention of anomalous renal artery as a cause of hydronephrosis is to be found in Rayer's "*Traité des Maladies des Reins*," 1842.¹ Of the fifty-two cases of hydronephrosis collected by Roberts in "*Urinary and Renal Diseases*," 1885,² two were due to this cause. Since the time of these early publications anomalous artery has come to be generally recognized as a definite cause of hydronephrosis. In the present literature the subject is given frequent consideration. Some of these later publications question anomalous artery as a primary cause of hydronephrosis. Geraghty and Frontz³ for example believe that almost invariably there is another cause present and that the enlarging pelvis folds over the artery simply as an incident in the pathologic process. Certainly it is a situation in which cause and effect are easily confused and that such is the sequence of events in some cases there can be no doubt.

Possibly the process is initiated in most cases by some degree of stasis from another cause, of itself unimportant or even temporary. As causes of such stasis may be mentioned functional disorders in the peristaltic activity of the ureter, insignificant narrowings, pregnancy and inflammatory processes. The frequency of anomalous renal artery without hydronephrosis proves conclusively that in most instances the contact with the ureter is without incident. A slight distention of the ureter and pelvis from any cause, however, even though it

be temporary, may so increase the pressure of contact that grooving and folding of the ureter begin. Such deformity becomes an independent cause of obstruction. Contact with the artery and increased uretero-pelvic pressure above this point are now mutually maintained. What was formerly an innocent vascular anomaly becomes an important factor in pathology.

Whatever may be the exact explanation of the pathologic physiology of the process it is a fact that the present literature records numerous cases in which this was the only cause of obstruction which could be determined. Quinby⁴ has recently reported six such cases. From the standpoint of the importance and frequency of anomalous artery as a cause of hydronephrosis the publication of Mayo, Braasch and MacCarty⁵ is most significant. In twenty-seven cases of hydronephrosis anomalous arteries were noted in twenty. In thirteen of these simple division of the artery cured the condition. That is to say anomalous arteries were present in 74 per cent and were apparently the cause of the disease in 48 per cent of the cases.

Most of the cases of this sort reported describe well established hydronephroses (pelvic capacities of 150 c.c. or more). From this general fact the inference is that no criteria for early diagnosis are available. As a result surgical treatment is delayed until extensive dilatation has ensued, marked impairment of function is manifest or the prolonged painful symptoms force resort to surgical exploration. This is undertaken in the hope, but not without misgiving, that a situation may be found correctible by a surgical procedure short of nephrectomy.

It is obviously to be desired that the presence of such offending renal arteries be recognized before they have wrought these extensive anatomical changes with entailed impairment of function and long period of suffering. It should be of value to point out clinical means of recognizing these cases while they are still in a condition well described as "stasis" and before they have advanced to the more extensive damage described as "hydronephrosis." The purpose of the present paper is to point out certain criteria to be found in the pyelogram which, taken in association with the other clinical features, permit a diagnosis of upper urinary tract stasis due to anomalous renal artery to be made with reasonable assurance and at an early stage of the process.

*Presented before the annual meeting of Minnesota State Medical Association, St. Paul, October, 1923.

In the present literature concerning anomalous artery obstruction there is not available any detailed and comprehensive consideration of all the features of the pyelogram which may be of value

this experience it is felt that the pyelogram almost regularly exhibits a congenital type of deformity of distinct diagnostic value not hitherto emphasized in this connection. The observations leading to the importance which is attached to this feature of the pyelogram may be best presented by reference to the clinical histories of the cases affording the observations. In this reference to cases clinical detail, completeness and sequence will be subordinated to development of the subject.

On careful dissection and examination of a hydronephrotic kidney (Fig. 1) removed at operation, three sets of vessels, an artery and vein in each case, were found entering the hilum anterior to the pelvis, a set at the upper angle, a set at the middle and a set at the lower angle. The last vessels lay in intimate contact with the uretero-pelvic junction, which they compressed and deeply grooved. The uretero-pelvic junction was hooked-up on these vessels and partially kinked over them. The dilated pelvis showed a dichotomous branching into upper and lower halves just at its entrance into the hilum. On section (Fig. 2), it was found that each intra-renal half gave off superior, middle and inferior calices, all of which were greatly dilated.

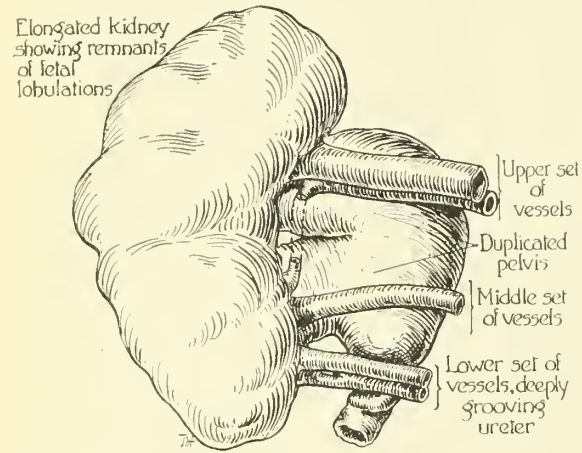

Figure 1. First case cited. Kidney removed at operation. Three sets of renal vessels. Those entering the lower angle of the hilum lie in intimate contact with the uretero-pelvic junction which they compress and deeply groove. There is well marked dilatation of the pelvis, which divides into upper and lower halves before entering the hilum.

in diagnosing the condition. Various writers, however, allude to certain individual features which may be of such value. For example Braasch⁶ speaks of and illustrates a "pyriform dilatation" of the pelvis as peculiar to anomalous artery obstruction. Sanes⁷ briefly mentions "pear shaped dilatation" as characteristic of the condition, but goes no further⁸ in describing this feature of the pyelogram. Crabtree⁹ gives particular importance to absence of filling of the uretero-pelvic junction area or demonstrable constriction in this region. He reports nine cases with reproductions of the pyelograms in which he considers such deformity to be present. Mention is frequently made of kinking and folding of the ureter as seen in the pyelograms of these kidneys.

Filling defects, demonstrable compression, kinking and folding of this sort, when present, are of great diagnostic importance, but in the early stages of the process may be well-nigh incapable of demonstration in the pyelogram. Pelvic or ureteral dilatation due to such incomplete obstructions probably occurs only after a considerable time and even when present is practically impossible to recognize as definitely characteristic.

During the past year a number of these cases have been encountered and carefully studied. From

Figure 2. First case cited. Cross section of same kidney shown in Figure 1. The lower set of vessels have been lifted away from the uretero-pelvic junction to show the grooving and effectual obstruction which they produce at this point. Slight enlargement and thickening of ureter below probably due to inflammatory change. Note the complete duplication of the intra-renal portion of the pelvis and extensive dilatation and thinning of kidney substance.

The earliest embryologic faults which we know could determine this anomaly of the pelvis were either the development of two ureteral buds from

the wolffian duct with later fusion of the stalks into a common pelvis and ureter or a prematurely early dichotomous branching of a single ureteral bud, each branch going on to the formation of three nor-

Figure 3. First case cited. Pyelo-ureterogram of kidney shown in Figures 1 and 2. Dilatation so advanced that detailed pelvic configuration can not be made out. No significant dilatation of ureter, but a fold, obstruction or filling defect at its junction with the pelvis is evident.

mally disposed major calices. In either case the development of the permanent vascular channels of this kidney followed the same early division as exhibited by the earlier fetal development of its partially duplicated pelvis.

Unfortunately the extensive dilatation of the pelvis in this case gave a pyelogram (Fig. 3) in which all detail of calyx configuration was obliterated, there appearing on the plate only large overlapping shadows of bromide solution. There is an apparent folding and possibly an unfilled groove at the uretero-pelvic junction. Such folding and filling defect, however, probably is of late occurrence in the process.

It was possible to compare the configuration of this pelvis, as seen after removal of the kidney, with the pyelogram of a previous case of anomalous renal artery obstruction. This patient had been operated on at a much earlier stage and before any appreciable dilatation had taken place. Severe and persistent painful symptoms over a period of five months and apparently characteristic of upper urinary tract stasis led to a kidney exploration. All available measures had excluded a diagnosis of calculus. Ureteral dilatations on the suspicion of

a ureteral stricture had failed to give relief and symptoms persisted after clearing up by lavage a mild pyelitis which had been present. At operation two sets of renal vessels were found, one set entering the upper angle of the hilum and one set entering the lower angle. The latter vessels crossed and lay in intimate contact with the uretero-pelvic junction. Unfortunately this patient's convalescence was marred by the formation of a perinephric abscess which was incised and drained. There was complete relief of symptoms.

Re-inspection of this pyelogram (Fig. 4) for purposes of comparison with the pelvic outline found by dissection in the later case showed a tendency to duplication of the pelvis. The definiteness of the anomaly, however, was by no means striking. It was scarcely comparable to the almost complete duplication seen in the latter case. Nevertheless it was now felt that possibly this feature of the pyelogram might have some significance in connection with the occurrence of anomalous vessels. Any filling defect or folding at the uretero-pelvic junction which might have been present would not show because of the presence of the catheter in the ureter.

Figure 4. Second case cited. Pyelo-ureterogram showing a tendency to division (reduplication) of the pelvis into rudimentary upper half and more nearly normal lower half. No defect at the uretero-pelvic junction is evident; possibly due to the splinting effect of the catheter which had not been withdrawn.

A third case afforded additional opportunity for observation. This patient had complained for two years of vague pain in the upper right part of the abdomen without typical radiation, but subject to

periods of considerable severity. There was tenderness in the right costo-vertebral angle. The pyelogram (Fig. 5) showed a partial duplication of the pelvis into a rudimentary upper half and more

Figure 5. Third case cited. Pyelo-ureterogram showing a rounded bulging true pelvis with partial duplication into small upper portion and larger lower portion. Overlapping or grooving of the uretero-pelvic junction is evident. Early hydronephrosis.

nearly normal lower half. Superior, middle and inferior calices were given off from each division and the whole pelvis showed a moderate degree of dilatation. Deformity at the uretero-pelvic junction was present, but its nature was not evident. A diagnosis of obstruction at this point due to anomalous renal artery was made on the basis of the partial duplication, of the pelvis, though it must be said without absolute confidence. At operation an anomalous set of vessels entering the mesial surface of the kidney, just below the lower angle of the hilum, was found. (Fig. 6.) They lay in intimate contact with the ureter, which they crossed just below the pelvis. At the point of contact the ureter was grooved and the dilated pelvis bulged above the constriction. Division of these vessels gave complete relief of symptoms.

A fourth case represented a much earlier stage in the process. The patient had experienced but one protracted attack of fairly typical pain which had lasted for five weeks and was still present. There had been slight bladder irritability. The only positive physical finding was tenderness of the right flank. The pyelogram (Fig. 7) showed a tendency to duplication of the pelvis. Again there was the

rudimentary upper division and more nearly normal lower division each giving off its calices. An unequivocal diagnosis of upper urinary tract stasis due to anomalous renal artery was made. At operation three separate arteries were found entering the hilum of the kidney. They were followed medially a distance of 3 or 4 cm., but were not found to join a common trunk. The vessel entering the lower angle of the hilum lay in intimate contact with the uretero-pelvic junction, but there was no groove and the pelvis did not bulge over it. Division of the vessel gave immediate and complete relief of symptoms. The day following operation the patient was able to say that she was completely free of the pain which had been constantly present during the previous five weeks.

These four cases are all examples of the same pathologic process. The ages of the four patients at the time of their first symptoms were nineteen, thirty-two, thirty-three and forty-six years. In all of them pain was the chief symptom. In three there was quite well localized tenderness in the flank though in none was a palpably enlarged kidney demonstrated. In two there were no urinary symptoms while in the others frequency of urination was noted. Pus cells in the urine varied in the four cases from a few to none at all. X-ray ex-

Figure 6. Third case cited. The kidney as found at operation, showing the contact of the anomalous vessel with the ureteropelvic junction. (Both a vein and artery were present; only the artery is shown in the sketch.)

amination of the uninjected kidney was negative in all.

This clinical picture conforms fairly well with that drawn by Quinby⁴ for anomalous artery ob-

struction and based on a series of cases with full and carefully taken histories. The picture is simply one of pain fairly well localized to the vicinity of the kidney and exhibiting a tendency to periodically increased severity together with definite ten-

cation of the pelvis varying from almost complete duplication to only a tendency to this anomaly. In two of the cases this feature of the pyelogram together with the general clinical picture of upper urinary tract stasis led to correct diagnosis before operation.

The finding of an anomalous renal artery as the cause of obstruction in all four cases came after other causes of obstruction had been excluded to the extent that they can be by modern methods in urology.

Figure 7. Fourth case cited. Pyelo-ureterogram showing slight dilatation of the pelvis. The terminal irregularities of the upper calices are well preserved. The apparent poor filling of the upper ureter may be due to decreased density of overlying gas in the intestine. The upper margin of this area of decreased density, however, corresponds to the position of contact of the anomalous vessel found at operation. Note the distinct tendency to duplication of the pelvis into small upper portion and larger lower portion. Compare with Figures 4 and 6. This relationship as to size of the upper and lower portions is the rule even with complete duplication including the whole pelvis and ureter, the upper portion usually being rudimentary.

derness in the flank. Except for these positive things the four cases presented little else in common. With such symptoms however the absence of stone, ureteral stricture or persisting infection and negative cystoscopic examination might be mentioned as significant negative findings common to all.

The degree of pelvic dilatation shown in the pyelogram was roughly proportionate to the duration of symptoms. In the first and third cases described symptoms had been present for six and twelve years respectively. In these the pyelogram showed, in the first, a well advanced hydronephrosis and, in the third, a well marked dilatation of the pelvis. In the other two symptoms had been present for a few months in one and a few weeks in the other. Only slight pelvic dilatation was evident in one.

In all four cases there was some degree of dupli-

Figure 8. For comparison. Pyelo-ureterogram. Normal pelvis and ureter.

Figure 9. For comparison. Pyelo-ureterogram. Distinct partial duplication without evident pathologic change. (Case of spontaneously passed minute calculi.)

It is not intended to give the impression that a tendency to duplication of the pelvis is thought pathognomonic of anomalous renal artery obstruction. It is possible to sharply distinguish between

Figure 10. For comparison. Pyelo-ureterogram. Bizarre type of renal pelvis. Possibly a tendency to duplication. Symptoms of upper urinary tract stasis.

the ideally normal pelvis (Fig. 8), perfectly formed and giving off superior, middle and inferior calices and the one showing partial division of the true pelvis into two halves each of which gives off separate calices (Fig. 9). Between the two, however, there are all gradations varying from a slight over-size of one major calyx to bizarre forms in which there is a tendency to duplication with usually one division rudimentary and the other predominant (Figs. 10 and 11). For these reasons duplication is necessarily a variable feature and relative term. Furthermore, while embryology gives good reason why vascular anomalies should follow pelvic anomalies the sequence is not invariable.

As mentioned above most of the cases of anomalous artery obstruction to be found in the literature describe fairly well advanced hydronephroses, many requiring nephrectomy. The explanation of this is not that these cases seek medical advice only in the late stages of the process, but that they are not recognized when first seen. In its early stages an obstructed point in the ureter from the contact of an anomalous artery is peculiarly difficult to demonstrate. It is a deformity or collapse from pressure without alteration of structure. There is

no point of narrowing to obstruct the passage of a catheter or to be felt with a bougie. There is no kinking of the ureter demonstrable by alterations in its course. The fluid injected for pyelography may sufficiently overcome the pressure to permit enough filling to obscure the collapse. For these reasons the obstruction is not recognized and if severe and typical symptoms do not force resort to surgery the process is allowed to go on. Eventually the later effects of obstruction are exhibited: greatly dilated pelvis, marked impairment of function and possibly infection. Exploration or nephrectomy is now warranted and refinements of diagnosis are of no practical value.

Cases exhibiting none of these extensive changes and well classified under the term "upper urinary tract stasis" present a very difficult problem in diagnosis. The feature of the pyelogram which has been described may be taken as a *criterion for the probable presence of an anomalous arrangement of the renal blood vessels*. Together with the absence of other demonstrable causes of obstruction

Figure 11. For comparison. Pyelo-ureterogram. Bizarre type of renal pelvis. The superior calyx is not well shown. It extends up over the twelfth rib, is distinctly oversized and possibly represents a tendency to duplication. Appendectomy for "Chronic Appendicitis." Symptoms of upper urinary tract stasis persist.

and a conforming clinical history it permits a diagnosis of obstruction from this cause to be made with reasonable assurance and before extensive damage has taken place.

DISCUSSION

DR. GILBERT J. THOMAS, Minneapolis: I am very much interested in the paper which Dr. Foley has presented. I have observed a rather large number of hydronephroses due to anomalous blood vessels. In my experience high obstructions in the ureter not caused by stone or demonstrable infection are caused by anomalous renal vessels. I have not observed the anomalies of the kidney pelvis in conjunction with anomalous renal vessels.

If Dr. Foley's observations are correct, he has given us additional data which will greatly assist in making an early diagnosis of hydronephrosis caused by anomalous blood vessel. In looking over the records of my recent cases, I find one which parallels Dr. Foley's reports. The lantern slide will show a pyelogram of the kidney. There are two pelves, one above the other, with no apparent communication. This is probably a double kidney. The lower pelvis is an infected hydronephrosis. The upper pelvis is not normal in outline although it is not pathological for anomalous or double kidney. The history in brief is as follows: Patient, female; age, 62 years. Three or four years ago a small lump was felt in the left flank. This was not painful and there were no other symptoms. About a year ago patient had a severe pain in her left flank and at this time the tumor seemed to enlarge. About three or four weeks ago she was seized with another attack of pain and the tumor again enlarged so that it was easily palpable. With the cystoscope we found two ureters on the left side, both of which were catheterized. I was unable to introduce the catheter into the lower pelvis, although sodium iodide could be forced into it. When we operated we found a large fluctuating mass which was somewhat adherent and which filled the entire flank and extended into the bony pelvis. With a trocar the contents of the tumor were aspirated and found to be infected fluid or urine. Slightly less than two quarts of this fluid was obtained. The ureter which opened into the lower end of the large pelvis was not small. About one-half inch below its exit, it was crossed anteriorly by a blood vessel about

twice the size of lead in an ordinary pencil. This vessel held the ureter against the distended pelvis. The vessel itself did not produce a kink where it crossed the ureter, but held it tightly against the pelvis so that the ureter in making a right angle turn just as it made its exit from the pelvis, was distinctly kinked. That part of the ureter above the vessel might have grown forward and downward so that a kink may have occurred where the vessel crossed. I think the obstruction in the ureter in these cases is caused by the ureter falling or growing over the vessel as a soft rubber tube might hang over a line and thus produce a kinking. Because of the poor condition of the patient, we were unable to dissect the complete blood supply to this double kidney. However, the ureter which drained the upper pelvis was free. Because of our inability to isolate the blood supply to the upper kidney, a total nephrectomy had to be done.

DR. WILLIAM F. BRAASCH, Rochester: In 1907 Dr. W. J. Mayo, together with Dr. MacCarty and myself, published a paper calling attention to the fact that anomalous renal blood arteries were a frequent cause of hydronephrosis. My urological friends have frequently questioned me on this subject, saying that they seldom, if ever, could find that anomalous blood vessels were the etiologic factors. I am glad that Dr. Foley in this very able paper could corroborate the frequency of this factor in the cause of hydronephrosis. I am certain that if surgeons would stop and look carefully for the cause of hydronephrosis, the anomalous blood vessel would be found more frequently. I have often seen Dr. Mayo stop and search for several minutes before he found the etiologic factor.

It is particularly of interest that anomalous blood vessels can be a factor in causing hydronephrosis, since they occur so often without obstructing the ureter. It is difficult to ascertain why they should constrict the ureter in some cases and not in others. In some cases at least it is found that the kidney assumes a position so as to permit of such ureteral obstruction.

There are, of course, a number of other causes of hydronephrosis and it would be very difficult to differentiate clinically between the various etiologic factors. Suffice to say that hydronephrosis resulting from anomalous blood vessel obstruction usually occurs in the younger adult and at the time that they attain their greatest anatomic development; in other words, between the ages of fifteen and twenty-five. It has been my experience that it is rather difficult to determine the exact etiologic factor by means of pyelography. Fortunately, it is not of much practical importance to do so, the main problem being to determine the existence of pelvic dilatation.

I would also call your attention to the fact that a pyelogram is not always necessary in the diagnosis of hydronephrosis. In fact, it should not be made where the diagnosis can be made without it, because every now and then, no matter what medium we use, if it is allowed to remain in the dilated renal pelvis, cortical abscesses may form. If the diagnosis can be made by means of withdrawing several ounces of residual urine from the renal pelvis through a ureteral catheter, there would be no object in making a pyelogram.

Probably the most practical factor for your consideration in Dr. Foley's paper is the comparatively frequent incidence of hydronephrosis. The condition is frequently and easily overlooked in the course of a general clinical examination because the urinary findings are negative in a large percentage of cases and the patient may have no urinary symptoms. Furthermore, the pain radiation is not necessarily suggestive of renal involvement and is in fact frequently more anterior than posterior. As a result, a large proportion of patients with hydronephrosis on the right side have had their appendix removed.

I wish to call your attention to the fact that with every lateral abdominal pain which is localized above the level of the umbilicus we should be very careful to rule out hydronephrosis. At the Mayo Clinic every patient that has an upper abdominal pain which is not otherwise identified by clinical data is referred to the urologist to rule out the possibility of hydronephrosis. This is probably one reason why we find so many cases of hydronephrosis annually. As I have said before, Dr. Foley is to be congratulated on the very careful study he has made of this interesting condition.

DR. WILLIAM J. MAYO, Rochester: Dr. Foley has made a real contribution to this subject. The first case of this type in which I operated was dramatic. In drawing up an infected hydronephrosis I didn't recognize an artery running into the lower pouch. These arteries usually run across in the vicinity of the uretero-pelvic juncture, and then well up on the posterior wall of the kidney. I cut this vessel and it dropped back and started a very smart hemorrhage. I finally traced the source of the hemorrhage, well down on the aorta. It was an entirely separate blood vessel and did not come off with the renal vessel.

Dr. Braasch has brought up a question of importance relating to the surgical phase: In what stage of hydronephrosis and with what amount of infection should we attempt to save the kidney? We have had some very interesting experiences in this respect. When I was abroad just before the war, I was asked to open a discussion on tuberculosis of the kidney. One of the most distinguished of the older members of the surgical profession of the country had given a detailed report of seven cases of tuberculosis of the kidney in which the bacillus of tuberculosis, and all the classical symptoms had been noted. These had afterward all disappeared, some without treatment, and some with treatment. The assumption was that for this reason tuberculosis of the kidney had existed, but that the patient had entirely recovered. However, there had been no cystoscopic examination made to show that there was urine coming from the affected side. My inference was that there was a dead kidney on that side, that is, a closed kidney without function, but still tuberculous.

The same point comes up in connection with hydronephrosis. Christian Fenger, who initiated the work on these structures at the uretero-pelvic juncture, and did not, at that time, recognize the relation of an anomalous artery to many of these conditions, was under the impression that an attempt should be made to save every kidney. Now the situation appears to be about this: if there is a perfectly good kidney on one side and a poor kidney on the

other side, if something is done to the poor kidney, for instance a procedure for relief of an obstruction which will relieve the patient of the immediate symptoms, it creates the belief that the kidney is functioning. Yet examination in the course of time will often show that there is no function on that side. If both kidneys are diseased and operation is performed on one kidney and it is saved, so long as function is necessary the poor kidney will continue to function. But if the kidney that has been operated on gets well, the second kidney will cease to function in a considerable percentage of cases. This is rather interesting because it shows nature's conservation in providing sufficient function. But if there is good function on one side and an advanced infected hydronephrosis on the other, even though an operation may relieve the patient of the pain and discomfort, it cannot be assumed, merely because the patient is relieved, that the kidney is functioning.

DR. A. C. STRACHAUER, Minneapolis: Since Dr. Braasch called attention to the presence of these anomalous vessels, surgeons in seeking the cause of hydronephrosis have found that these vessels are of rather common occurrence. There is nothing uncommon about an anomalous vessel crossing the uretero-pelvic juncture and causing an obstruction. I do, however, want to call your attention to the fact that occasionally these vessels are obliterated, and instead of a vessel you find a cord, a cord so definite that you can snap it under the finger. The pyelogram may definitely show a grooving, in early cases; and the release of this, the division of the cord, of course accomplishes the same result that the division of the blood vessel would.

The pyelogram in these cases of obstruction due to either blood vessel or cord from the obliteration of the vessel, should be carefully studied. Occasionally it will be found that the uretero-pelvic juncture instead of being at the most dependent portion of the hydronephrosis sac has been carried up on the side; and there is a certain amount of residual urine in the pelvis. Under these circumstances, in my opinion, the kidney should be decapsulated and a nephropexy performed, the capsule used as ligaments. Care should be taken that no fat comes between the decapsulated kidney and the muscle along the last rib. The kidney is so fastened that its longitudinal axis is changed to a more transverse position, so that the urine drains into the ureter from the pelvis at its most dependent portion.

DR. ARNOLD SCHWYZER, St. Paul: I think I never saw as nice and clear an x-ray picture as in the first picture the Doctor showed us. The relief from the obstruction that one gets by the cutting of an abnormal artery is not always satisfactory. Though we have heard that a nephrectomy is the classical treatment for these conditions, I would like to take another standpoint. The trouble was that we had only the linear method of uretero-pyelo-plasty, the methods of Fenger, Morris, etc. They all simply split the region where we had a stricture or had a kink and united transversely. We see in their illustrations there was a good deal of puckering and in the course of healing a fistula easily forms. In three cases I tried to improve on

that and I am sure I have. If you have a kink at the pyelo-ureteral junction, in releasing the parts from fixing strands you can always stretch it. I then make an incision, a Y-shaped one, with one of the three legs down through the strictured ureter and the other two in the pelvis of the kidney, spreading apart at an angle of 60 degrees. I can now take the flap between these two pelvic branches of the Y down to the end of the lower incision and leave the puckering in the wide part of the pelvis of the kidney. The opening was funnel shaped. In three such cases we had a satisfactory result—one case was not a very good one for the method. It had been operated upon elsewhere by dividing an abnormal vessel but had not had any relief. The relief as long as I could observe the case was marked; but I heard that the patient died a year later from a ruptured extrauterine pregnancy.

The other two cases were one in a young child and one in a young woman. I have not made a cystoscopic examination since, but the two cases have an absolutely clear urine and have had a complete recovery. I always feel that though the surgeon defends that a nephrectomy in these cases is right, he does not feel quite right just the same in the bottom of his soul, when he sees a healthy looking kidney cut out on the table even if this healthy kidney has a large pelvic sac. He cannot feel right.

DR. FREDERIC E. B. FOLEY, St. Paul (closing): I wish to thank those who have discussed my paper for adding so much to its interest.

Figure 12. Case cited in closing discussion. Pyelo-ureterogram typical of the so-called bifid pelvis. Although representative of a type of pelvis generally considered normal, the embryologic fault which explains its configuration is doubtless the same as in the case of complete duplication.

If there is time available I will add very briefly another case to those presented in the paper. This patient was not encountered, or at least was not operated upon, until after the preparation of the paper.

A young woman 29 years of age. Ten years ago she had what was probably a Neisser infection; three curettements had been done for "endometritis." Tonsillectomy

three years ago. Gall bladder and appendix removed two years ago. X-ray treatments of a small fibroid in cervix of uterus a year and a half ago.

Her complaint at the time of admission was of frequent painful urination and pain throughout the left side of the abdomen and in the flank. She gave a history of having had periods of this sort of left sided pain for several years. The present attack was the only one associated with bladder symptoms and these began during an attack of influenza before admission.

Physical examination was essentially negative except for very definite tenderness in the left costo-vertebral angle, and tenderness felt on palpation of the flank and along the course of the ureter. A small fibroid was felt in the anterior part of the cervix above the vagina. There were temperature elevations to 99° each day. Many pus cells in the urine.

Figure 13. Case cited in closing discussion. The kidney as found at operation, showing the premature branching of the renal artery. The premature branch girdles the uretero-pelvic junction to gain access to the posterior lip of the sinus renalis.

On cystoscopic examination the trigone was seen to be reddened; there was inward displacement of the bladder floor just beyond the trigone due to the fibroid nodule in the cervix. No. 5 catheters passed without resistance on each side. The urine from the left kidney contained an occasional clump of pus cells.

Repeated bladder urine examinations for tubercle bacilli were negative and guinea pig inoculations of the ureteral catheter specimens were also negative.

Treatment consisting of forcing fluids, urinary antiseptics, bladder lavages and lavages of the left renal pelvis gave no persisting improvement. As a result of her distressing symptoms the patient had lost 40 pounds at the end of six months; with this weight loss the left sided pain had become worse. The left pyelogram which had been made at one of the early cystoscopies several months ago was recently re-inspected, figure 12 (shows slide). It shows a very definite partial duplication. A diagnosis of

upper urinary tract stasis due to anomalous renal artery was made. Figure 13 (shows slide) shows the arrangement of the anomalous artery as found at operation. There has been complete relief of the left sided pain since operation. The bladder irritation was relieved for a time but has recurred. It is believed that an infiltration of the bladder neck in relation to the small fibroid (possibly infected) is responsible.

This condition can be easily overlooked at operation unless the surgeon has in mind anomalous vessel as a cause of upper urinary tract stasis without hydronephrosis. The vessel at first is obscured by fat. This is removed and the vessel is seen but with the kidney drawn down into the incision it lies across the pelvis. Push the kidney up into normal position and immediately it is apparent that the vessel lies in very intimate contact with the ureter.

My experience with the diagnosis and treatment of cancer covers a period of almost thirty-one years and can be easily divided into four decades. The effect of the absence of any educational effort is most marked in the first decade up to 1900 and continued to almost 1910. The educational effort began in 1910. The effects were seen within a few years. They are most marked since 1920.

When we compare the results of our records in the first ten years up to 1900 with those since 1920, we may summarize them as follows:

These figures come from the Surgical Pathological Laboratory of the Johns Hopkins Hospital, where we have forty thousand records. These figures include all the cases treated in the Surgical Service of Johns Hopkins Hospital and of St. Agnes Hospital in Baltimore, and during the past five to eight years about one-third of the material has been received from outside sources. But from the very beginning there has been a large amount of material with good records received from physicians and hospitals throughout this country. Our records therefore pretty clearly show the falling curve of inoperability and the rising curve of five-year apparent cures and longer permanent cures.

This improvement is most marked in cancer of the mouth, skin and breast. It is beginning to be marked in cancer of the cervix. There is very little improvement in cancer of the stomach and colon.

Breast. In the first ten years inoperable cases registered almost 40 per cent. The per cent of cancer as compared with benign lesions was almost 80 per cent. The per cent of women seeking examination in whom nothing definite was found in the breast was less than 1 per cent. The per cent of five-year cures in operable cases registered about 20 per cent.

In my own clinic since 1920 the number of women seeking examination at which nothing definite is found has risen from less than 1 per cent to more than 50 per cent. Inoperable cases have fallen from more than 40 to 5 per cent while the per cent of cancer has fallen from 80 to 50 per cent. These changes are associated with the one controllable factor—the duration of the lump known to the patient. In the first ten years the average duration of the lump was almost two years. Since 1920 it has fallen to less than nine months. Our records show that women need no instruction, as to the warning of trouble with the breast. With rare exceptions they are warned in time—they feel the lump, observe the retracted nipple, or the dimpled skin, but they need education to *act* in time.

Tongue. In the first ten years but one patient sought the advice of the clinic for a lesion of the tongue which was not

cancer—about 3 per cent. Today, in my own clinic more than 70 per cent come under observation with leucoplakia, areas of irritation, ulceration, ragged dirty teeth—that is in the stage before cancer has developed, and a period in which cancer can be prevented by the removal of the irritating factors—tobacco and ragged, dirty teeth.

This is the most remarkable effect of the educational effort. In addition, inoperable cases have decreased, and early cancer of the tongue with a probable cure of almost 70 per cent has increased.

Up to the present time the educational efforts have been carried on by a very small minority. There seems no difficulty in getting space in the daily press or magazines, but the efforts are more or less sporadic. It does not seem to be a question of writing the message to the people so it will be read—it seems to be largely a question of multiplying the number in the Medical and Dental Professions who will aid in the teaching efforts and of increasing their efficiency in this new and very essential part of the practice of Medicine.

To eradicate disease such as cancer there must be a very efficient organization. Some diseases can be eliminated by providing good water and food; others can be prevented or cured by a serum. But there is no treatment that offers much for late cancer, and there seems to be no way of getting cancer under treatment in its earliest stages, except by getting to the people a definite, clear-cut message. We must also remember that cancer of the mouth and of the skin, and perhaps cancer of the cervix, are preventable diseases. A cancer of the breast without involvement of the axilla offers 70 per cent chances of a cure, while with the involvement of the axilla this falls to 20 per cent. The duration of the indigestion or discomfort known to the individual in cancer of the colon and stomach is far too long before the thorough examination with the x-rays. My recent evidence shows that many cancers of the colon originate in benign polypoid growths. These growths give definite symptoms in the benign stage and can be felt with the finger, can be seen with the proctoscope, or outlined with the x-rays. In this stage the only failure to cure would be due to operative mortality.

It is therefore the obligation and opportunity of members of the Medical Profession who are also members of the Society for the Control of Cancer to bring these life-saving facts to their own patients, their own colleagues and their own communities.

Sincerely yours,

JOSEPH COLT BLOODGOOD.

From a letter to the New York Committee of the American Society for the Control of Cancer.

Life Insurance Examiners

In this issue of MINNESOTA MEDICINE appear four articles by medical directors of four of the leading life insurance companies of America. The presentation of these addresses was suggested by Dr. C. N. McCloud, Medical Director of the Minnesota Mutual, in an effort to acquaint the profession of Minnesota with some medical facts in regard to life insurance. That such a ready response was forthcoming on the part of four large insurance companies to the request of a county society located in the middle West, is significant of the appreciation on the part of the companies represented of the need of a better understanding of the insurance viewpoint by physicians.

A large percentage of the profession examine for one or more life insurance companies. An enormous sum is paid yearly to the medical profession for services in this connection. Nevertheless few physicians as a matter of fact ever acquire the insurance viewpoint and make good examiners. There is a tendency on the part of the average examiner to slide over certain questions which to him seem absolutely useless and do rather slipshod work.

There is some excuse for the impatience in filling out forms often manifest. Many of those we are required to fill out in connection with insurance work of various kinds are needlessly long and exacting, at times to the point of absurdity. It can be safely said, however, that the medical application blanks of the large insurance companies have been evolved after years of experience and pretty carefully boiled down. Several questions are necessary purely from a legal standpoint. The questions regarding the use of alcohol are in point. Dr. Wenstrand's article showing the actuarial statistics in light, moderate and heavy drinkers are doubtless illuminating to most of our readers. The actual influence on life expectancy is doubtless greater than shown in the chart mentioned for it is human nature to minimize one's questionable habits when applying for life insurance.

We recommend the reading of these insurance articles by all those interested in this kind of medical work. This phase of medical activity has been neglected in the past. Who knows but that the Ramsey County Medical Society has blazed a trail which will be profitably followed by other and larger societies.

State Boards

The intention primarily in inaugurating State Board Medical Legislation was the raising of the standards of the medical colleges, and only secondarily, of necessity, the improvement of the medical personnel of the profession as represented by the graduates of these colleges.

When medical legislation started some thirty-five or forty years ago, medical colleges were in the main commercial institutions. No preliminary demands were made in reference to mental training. Some of the better colleges named a high school course as a requisite, but it was not a rigid requirement. Only a meagre few demanded more than two terms of barely six months each in medical college before granting a diploma as an M.D. Commercialism was the rule, quantity production the desire, and quality not considered. At one time the United States had one hundred and seventy-five medical schools, more than all the rest of the world.

The spring school poison was also injected into the unfortunate condition of medical affairs, so that it was possible for an illy educated individual often with barely grammar school preliminaries to enter

a so-called medical school in October, remain until March, enter a spring school, graduate in June and be a legal M.D. Instances of this kind were numerous. The conditions became intolerable.

Some of the forward looking medical men in Minnesota studied the question, and concluded that some form of legislation was essential and the fundamental starting point was in the changing of medical college standards. The law of 1887 was evolved and three years of at least six months each in a recognized medical school was demanded of each applicant for examination. This met with violent opposition by the medical schools and two of our now foremost institutions began suit to test the constitutionality of the law. The law, however, was executed without favor and gradually all medical schools adopted the three-term standard. Improvement in methods and development in medical knowledge made more time in medical school necessary to grasp enough knowledge for efficiency, so that in 1899 the law was changed to demand four terms in medical college. The colleges all came up to this standard in time. Not until 1912 was the preliminary demand of two years in a College of Liberal Arts over and above a high school course, put in operation. These demands are now made by all Class A colleges.

A provision in the Minnesota Law divorced the personnel of the board entirely from any medical school. No person connected with a medical school could be a member of the Board.

The law should be as brief, mentioning only main principles. Many laws are so filled with detail the board cannot function unless every act is mentioned in the law. There should be some reserve power left for the board to cover any new issue that the passage of time may bring forth.

The different medical cults have caused much confusion in the control of medical legislation. The danger to the public in this lowering of medical standards has not been appreciated by the people. The law is intended for the benefit of the people and not for the medical men as a class. This should always be made prominent, as many assume that it prevents their exercising their liberty of choice as to who shall treat them and how they shall be treated. With the basic fact established that the law intends only to cover the fact of proper educational qualification, both as to certain necessary preliminary education and a high grade medical education, the manner or method of

treatment can be left entirely as a matter of choice. The question of the standardizing of the qualification of all who treat the sick is basic and will eventually prevail. As a compromise many states are attempting to function with a conjoined board, all kinds of treatment being represented on one board. This is a mistake and can only be carried out by lowering the general standards of medical qualification and confusing the public. While the recognizing of each cult by a board is to be deplored, that is far better than the conjoined board. They have to stand or fall by what they deliver to the public and should not be dignified by association with those who have genuine medical and primary training. Three or four standards of qualification in one law have been found most undesirable. Many cannot disassociate medical treatment from a species of necromancy or miracle working, while long training and deep study on the part of the medical man is the only method of making a safe and sane practitioner. This basic fact accepted, there is no place for the conjoined board.

T. McD.

Doctor of What?

"Once upon a time many years ago, when our grandfathers were little children, there was a doctor; and his name was Doolittle—John Doolittle, M.D. 'M.D.' means that he was a proper doctor and knew a whole lot."

So begins one of the popular Doolittle books and the above furnishes a suitable text for some cogitations. Once upon a time the title of doctor meant something. It signified as a rule some attainment in the field of medicine or the ministry. Not so now. Any one of a variety of duly licensed institutions may dispense a degree of doctor of this or that. And with the recent influx of quasi-medical doctors such as naturopaths, chiropractors et al, the title of doctor has come to carry with it a certain amount of opprobrium.

The title doctor may designate a clergyman, D.D.; physician or surgeon, M.D.; professor, Ph.D., D.D., or LL.D.; dentist, D.D.S.; veterinary, V.M.D.; osteopath, D.O.; chiropractor, D.C.; naturopath, N.D.; et cetera ad nauseum, and is anything but discriminating. The recent disclosures of the "diploma mills" have only served to further depreciate the term doctor, so much so that we are informed the California state board of medical examiners is contemplating legislation to abolish the

term doctor entirely and to require the use of the initials, M.D., D.D., and so forth. More legislation, and fantastic legislation at that; for, unless nationwide, no relief for the situation will be afforded.

There seems to be no word in the English language which quite designates the M.D. The word physician is not ordinarily used to include the surgeon. The phrase "physician and surgeon" is too cumbersome. In England the surgeons are plain Mist'ers.

We shall probably never shake off our doctor titles. While the M.D. stands for doctor of medicine, and few of us would want to be known primarily as prescribers of medicine, the initials represent our degree and should be more generally used. We would bequeath without a tear the abbreviated title "Doc" to any or all of the many present day half doctors.

OBITUARY

DR. JAMES McAULIFFE

Dr. James McAuliffe of Duluth died at the age of 66 years at St. Mary's Hospital, Duluth, March 23, 1924.

Dr. McAuliffe was born at Olean, New York, where he spent his early years. He was graduated from Buffalo Medical College, Chicago, and took a post-graduate course at Bellevue Hospital, New York, specializing in eye, ear and nose diseases. In 1887 he came to Duluth and practiced there until the fall of 1922, when he suffered a stroke while out hunting.

He had been confined to the hospital practically ever since, with the exception of a short time when he was able to leave and reside in his rooms at the Lenox Hotel, where he had made his home for a number of years.

Dr. McAuliffe was a member of the local council of Knights of Columbus, in which he took an active part for a number of years. He was the examining physician for Duluth for the order for many years. He was also deputy coroner and acted as coroner during the late war, when Coroner Charles F. McComb was away in service. He was a member of his county and state medical associations.

Surviving are his son, James, and a brother, John J. McAuliffe, Duluth, and five brothers and two sisters in Olean, New York.

The following tribute paid Dr. McAuliffe through the columns of a home paper gives evidence of the esteem in which he was held in his own community:

"In the passing of Dr. McAuliffe Duluth has lost one of its finest citizens. He died richer in friendship than most men, through his skill as a physician and surgeon, his self-sacrifice for others and his devotion to the welfare and happiness of the members of the circle within which he lived. He died poorer in worldly possessions than most men, because of his honesty, his self-sacrifice and his

willingness to serve the poor and the little ones in this world without pay, at any time during night or day, no matter what conditions existed.

"In his kind, benevolent way, he exemplified the highest ideals of that church to which he belonged. He was a servant and follower of Jesus Christ, and he gave unstintingly of himself and of what little he possessed to those in need. The cheer and the comfort that he brought in the home of sickness and death will never be forgotten by those who knew him and whom he served.

"As a physician he occupied a position attained by few. He was careful, reliable and efficient, and his standing among his brother physicians was unequalled. Doctors Charles and Will Mayo of Rochester considered him most reliable, and his word and diagnosis were taken by them as authoritative. He was considered one of the most reliable and dependable physicians in the St. Louis County Medical Society."

DR. O. K. EGGEN

Dr. O. K. Eggen was born in Levanger, Norway, in 1882 and came to America with his parents at the age of three. He attended the Red Wing Seminary for four years and Hamline University two years, before going to Philadelphia for his medical work at the Jefferson Medical College, where he was graduated in 1909.

After this he began practice in Minneapolis, where he had remained ever since, being on the staff of St. Mary's Hospital. He was an office associate of Dr. Joe M. Neal.

Dr. Eggen married Miss Anna Hart in 1914. Her death occurred one year ago. Dr. Eggen was a member of the Court of Honor Lodge and of the County and State Medical Societies and the American Medical Association.

On March 26th he was struck by an automobile and died the next day as the result of his injuries. He is survived by three sisters, Mrs. Glaeser of Minneapolis, Mrs. Orstad and Mrs. Mortret of Ottawa, Iowa, and by two brothers, John and Carl Eggen of Edmonton, Canada.

DR. LYMAN P. FOSTER

Dr. L. P. Foster, 88 years old, a resident of Minneapolis since 1848 and one of the oldest practicing physicians in that city, died at his home in April, 1924.

Dr. Foster was born in Pittsburgh, November 5, 1836, and with his parents came to St. Anthony Falls in 1848. In 1853 he attended the first session of the University of Minnesota. He had lived in Minneapolis continually since that time, remaining active in his practice until a few weeks before his death.

Graduating from Duff's College, Pittsburgh, in 1856, Dr. Foster returned to Minneapolis and in 1858 was admitted to the Minnesota bar, beginning practice as an attorney in 1860 at St. Anthony Falls. In 1873 he attended Rush Medical College and Hahneman Medical College, both in Chicago. He was assistant professor at the Hahneman College in 1881 and 1882.

For many years Dr. Foster was active in church work. He was ordained an elder in the Methodist Episcopal Church in 1874.

Surviving are his widow and four daughters.

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

SOUTHERN MINNESOTA MEDICAL ASSOCIATION OFFICERS

Dr. F. P. Strathern, St. Peter, president.
Dr. C. J. Holman, Mankato, first vice-president.
Dr. A. Gullixson, Albert Lea, second vice-president.
Dr. H. T. McGuigan, Red Wing, secretary-treasurer.

PROGRAM COMMITTEE

Dr. H. W. Meyerding, Chairman, Rochester.
Dr. F. C. Heise, Winona.
Dr. F. R. Huxley, Faribault.

EXECUTIVE COMMITTEE

Dr. W. F. Braasch, Chairman, Rochester.
Dr. J. W. Andrist, Owatonna.
J. S. Holbrook, Mankato.
COMMITTEE ON ARRANGEMENTS FOR MANKATO MEETING
Dr. J. T. Schlesselman, Chairman, Mankato.
Dr. C. C. Pratt, Mankato.
Dr. A. G. Liedloff, Mankato.

The annual meeting of this association will be held at Mankato, Monday, May 19, 1924. The scientific program will be called at 8:00 A. M. The annual business meeting will take place at 5:30 P. M. Following the banquet at 6:30 P. M. the association will be addressed by Dr. Dean Lewis, of Chicago, and Dr. W. J. Mayo.

Members of the profession are invited to attend the meetings and provision is being made to entertain visiting ladies.

Dr. J. T. Schlesselman, Mankato, has charge of hotel and banquet reservations.

The following interesting program has been arranged:

1. RADIUM IN BENIGN CONDITIONS OF THE NOSE AND THROAT. Dr. Laura A. Lane, Minneapolis. Discussor: Dr. B. E. Hempstead, Rochester.
2. LARYNGEAL OBSTRUCTION IN ACUTE INFECTIOUS DISEASE. Dr. S. W. Adler, Winona. Discussor: Dr. Walter Ramsey, St. Paul.
3. INTUSSUSCEPTION IN INFANCY. Dr. W. B. Grise, Austin. Discussor: Dr. F. C. Rodda, Minneapolis.
4. THE ROLE OF DIET IN THE TREATMENT OF DISORDERS OF OLDER CHILDREN. Dr. Frederic Wm. Schlutz, Minneapolis. Discussor: Dr. H. F. Helmholtz, Rochester.
5. HYPERTENSION: AN INDEX TO TOXEMIA OF PREGNANCY. Dr. R. D. Mussey and Dr. L. M. Randall, Rochester. Discussor: Dr. J. C. Litzenberg, Minneapolis.
6. SOME NEW PROBLEMS IN OBSTETRICS. Dr. W. H. Condit, Minneapolis. Discussor: Dr. John L. Rothrock, St. Paul.
7. FACTORS IN OPERABILITY OF ACUTE APPENDICITIS. Dr. W. P. Finney, Rochester. Discussor: Dr. A. C. Strachauer, Minneapolis.
8. PRE-OPERATIVE AND POST-OPERATIVE CARE OF SURGICAL PATIENTS. Dr. A. E. Sohmer, Mankato. Discussor: Dr. W. W. Walters, Rochester.
9. TREATMENT OF NASAL DEFORMITIES. Dr. G. B. New, Rochester. Discussor: Dr. Carl Waldron, Minneapolis.

10. OSTEO-CHONDRAL GRAFTS TO SKULL. Dr. A. M. Hanson, Faribault. Discussor: Dr. A. R. Colvin, St. Paul.
11. FOREIGN BODIES IN THE ESOPHAGUS AND AIR PASSAGES. Dr. P. P. Vinson, Rochester. Discussor: Dr. K. A. Phelps, Minneapolis.
12. PNEUMONIA AND ITS TREATMENT WITH PNEUMOCOCCUS ANTIGEN. Dr. D. B. Pritchard, Winona. Discussor: Dr. E. C. Rosenow, Rochester.
13. CLINICAL ASPECTS OF CORONARY SCLEROSIS. Dr. F. A. Willius, Rochester. Discussor: Dr. J. S. Gilfillan, St. Paul.
14. HIP FRACTURES. Dr. A. G. Liedloff, Mankato. Discussor: Dr. H. W. Meyerding, Rochester.
15. INJURIES OF THE CARPAL BONES. Dr. Emil S. Geist, Minneapolis. Discussor: Dr. C. C. Chatterton, St. Paul.
16. TREATMENT OF BURNS. Dr. Arthur Collins, Duluth. Discussor: Dr. A. W. Ide, St. Paul.
17. THE VALUE OF PROCTOLOGY IN GENERAL PRACTICE. Dr. L. A. Buie, Rochester. Discussor: Dr. W. A. Fessler, Minneapolis.
18. X-RAY THERAPY ON SOME COMMON SKIN DISEASES. Dr. A. J. Wentworth, Mankato. Discussor: Dr. W. H. Gockerman, Rochester.
19. SURGICAL TREATMENT NON-TUBERCULAR PULMONARY SUPPURATION. Dr. C. A. Hedhloim, Rochester. Discussor: Dr. F. W. Wittich, Minneapolis.
20. ROLE OF IODINE IN PREVENTION OF GOTTRE. Dr. Henry S. Plummer, Rochester. Discussor: Dr. C. H. Mayo, Rochester.

MINNEAPOLIS CLINIC WEEK

Minneapolis Clinic Week will be held Tuesday, Wednesday, Thursday and Friday, May 6, 7, 8 and 9, with headquarters at the Radisson Hotel. The first two days, May 6 and 7, will be devoted to dry clinics to be held in the Unitarian Church, Eighth St. and La Salle Ave. The following days, May 8 and 9, will be devoted to clinics at hospitals from eight o'clock until noon. The afternoons will be given over to the presentation of dry clinics in the Gold Room at the Radisson Hotel. Any physician from outside the Twin Cities may send in his patient for a dry clinic demonstration.

Minneapolis Clinic Week is to be closely associated with the Minneapolis Health Exposition which will be in operation from May 3 to 12 at the Armory Building, Minneapolis, where the various phases of public health work, educational work related to public health measures, and commercial exhibits related to both will be carried on.

The Annual Banquet given by the Hennepin County Medical Society will take place the evening of Wednesday, May 7th, at the Radisson Hotel.

ANNUAL HEALTH EDUCATION CONFERENCE

At the invitation of the Massachusetts Institute of Technology, a working conference in Health Education is to be held June 23-28 at Cambridge, Massachusetts. The conference called by the Health Education Division of the American Child Health Association will be limited to 100. Registration must be made in advance. Address Emma Dolfinger, 370 Seventh Avenue, New York City.

THE NORTHWESTERN MEDICAL OFFICERS' ASSOCIATION OF THE WORLD WAR

A meeting of the Northwestern Medical Officers' Association of the World War will be held Tuesday evening, May 6, 1924, at 6:30 o'clock at Schiek's Cafe, Minneapolis. The meeting will consist of a dinner to be followed by entertainment. The address of the evening will be given by Mayor George E. Leach, of Minneapolis. Any medical officer who saw service in the World War is eligible to membership in the Society and is urged to attend the meeting. Dr. Stanley R. Maxeiner, 301 Physicians & Surgeons Bldg., Minneapolis, is in charge of reservations.

SOUTHWESTERN MINNESOTA MEDICAL SOCIETY

The regular meeting of the Southwestern Minnesota Medical Society will be held Thursday, May 22, 1924, at Luverne, Minnesota. The program includes the following addresses.

President's Address—Dr. G. G. Balcom, Lake Wilson.

"Pyelo-Ureteritis of Pregnancy"—Dr. E. L. Perkins, Sioux Falls, S. D.

"Gastric and Duodenal Ulcer"—Dr. A. E. Booth, Minneapolis.

Case Report—Dr. L. M. Gerber Ditmeier, Jasper.

AMERICAN MEDICAL ASSOCIATION

The official call to officers, fellows and members of the American Medical Association for the annual meeting to be held this year in Chicago has been sent out.

The House of Delegates will convene on Monday, June 9th, the sections meeting Wednesday, Thursday and Friday morning, June 11, 12 and 13.

Minnesota's two delegates are Dr. J. L. Rothrock, St. Paul, and Dr. J. C. Litzenberg, Minneapolis, the alternates being Dr. J. F. Corbett, Minneapolis, and Dr. O. W. Parker, Ely.

LYMANHURST SCHOOL FOR TUBERCULOUS CHILDREN

The following program will be presented before a meeting of the Lymanhurst and Parkview medical staffs at the Lymanhurst School, Minneapolis, Tuesday evening, May 27, 1924, at 7:00 o'clock:

Twenty Years' Observation of Tuberculosis Control—Dr. E. L. Tuohy, President of the St. Louis County Tuberculosis Commission, Duluth, Minn.

Report of Von Pirquet Tests in 1,500 Children in a Minnesota Rural Community—Dr. S. A. Slater, Superintendent, Southwestern Minnesota Sanatorium, Worthington, Minn.

All persons interested in tuberculosis are invited to attend this meeting.

OF GENERAL INTEREST

Dr. and Mrs. Paul O'Leary have returned from San Antonio, where they spent the winter.

A class of twenty-four nurses was graduated from Eitel Hospital, Minneapolis, Friday evening, April 25.

Dr. and Mrs. C. Darcy Wright of Minneapolis have returned from Florida, where they spent the winter.

Dr. F. G. Kohler, formerly of Hector, is now located in Minneapolis, where he has opened offices in the McKnight Building.

Dr. P. P. Vinson, Rochester, spoke before the sectional meeting of the American College of Surgeons in Columbus, Ohio, March 24.

Dr. J. A. Wilkins, who has been at the Mayo Clinic for several years, has gone to Norfolk to enter the practice of internal medicine.

Dr. Gordon B. Kamman of Saint Paul is now associated in the practice of his profession with Dr. C. E. Riggs in the Hamm Building.

Dr. J. G. Meisser, who has been associated with Dr. Roscnow for several years, has left for Cleveland to work with Dr. Weston A. Price.

Dr. W. O. Ott, who was Dr. Adson's assistant at the Mayo Clinic, has announced his connection with the Harris Clinic of Fort Worth, Texas.

Dr. W. H. Hengstler, formerly of Saint Paul, is now in California, where he contemplates making a permanent location for the practice of medicine.

Dr. A. J. Clay of the Clinic of Drs. McGregor, Hanna and Clay of Fargo, N. D., has left for Barnes Hospital, St. Louis, Mo., where he will take a month's course in insulin treatment of diabetes.

Dr. F. W. Gaarde and Dr. R. M. Wilder, of Rochester, attended a meeting of the Billings Club in Chicago, April 1, at which the seventieth birthday anniversary of Dr. Billings was celebrated.

Dr. R. D. Carman gave a memorial address at the services held last month at Washington University for Dr. Walter Mills, with whom he had been associated in his earlier work with x-ray.

Dr. Carl M. Oberg, Minneapolis, left for Europe May 1. After a few weeks' travel in the Scandinavian countries, he will go to Vienna to attend the clinics there. Dr. Oberg expects to return in October.

Dr. A. A. Rankin, formerly of Waconia, is now located at Brownston, where he has taken over the practice of Dr. O. J. Engstrom. Dr. Engstrom is now associated in practice with Dr. E. H. Smith at Bemidji.

Dr. Paul D. Berrisford, Saint Paul, addressed the Washington County Medical Society at Stillwater, March 11, on the subject "Acute Infection of the Nasal Accessory Sinuses" with lantern slide illustrations.

Dr. A. W. Jones, of Red Wing, who has been a member of

the board of education of that city for fifteen years and president of the board for four years, has declined renomination and will retire at the May meeting.

Dr. M. F. Guyer, Professor of Zoology, University of Wisconsin, gave the fifth in the series of lectures on heredity under the auspices of the Mayo Foundation and its chapter of Sigma Xi, Friday, March 28. His subject was "Eugenics."

Dr. William Clark and his associate, Dr. Eugene J. Asnis, of Philadelphia, spent the week of April 7 to 14 in Rochester, and gave Mayo Foundation lectures on April 10 and 11 on electrodesiccation and coagulation in the treatment of neoplastic disease.

Dr. and Mrs. Orville N. Meland, formerly of Warren, now of Saint Paul, have returned from a trip abroad. They spent the winter in London, Paris and Vienna, where Dr. Meland attended the various clinics, and before leaving visited for six weeks on the Riviera and in the principal Italian cities.

Dr. Wallace H. Cole, Saint Paul, addressed the March meeting of the Minnesota Pathological Society on "Asymmetrical Chondrodysplasia with Report of a Case." Other papers given were "Dwarfism" by Dr. Wm. A. O'Brien, Minneapolis, and "Blastomycotic Meningitis with Report of a Case" by Dr. L. R. Gown, Minneapolis.

Professor A. E. Stewart, professor of agricultural physics at the University of Minnesota, will speak on "The Essentials of Fresh Air" with illustrations by lantern slides Tuesday evening, May 6, during Health Week at the Minneapolis Armory. Ventilation in the modern home will be one of the features of Professor Stewart's address.

In an effort to increase the circulation of Hygeia a letter was recently sent to the secretary of each county society in Minnesota urging them to take up the matter of a Hygeia publicity committee with their local society. A county society can further the proper kind of medical publicity in no better way than taking a group subscription to Hygeia and placing Hygeia on the reception room table in each member's office.

The Samuel D. Gross prize of \$1,500 is offered this year for the best original essay illustrative of some subject in surgical, pathological or medical practice founded upon original investigations. The essay must be written by a single author in English and should be sent to the Trustees of the Samuel D. Gross Prize of the Philadelphia Academy of Surgeons, care of the College of Physicians, 19 South 22d Street, Philadelphia, on or before January 1, 1925. The competition is open to American citizens only.

The March number of MINNESOTA MEDICINE contained a short account of the Benjamin Franklin fund and the award to one Pierson W. Banning of Los Angeles of 2,500 pounds for his published work, "Mental and Spiritual Healing." Most of our readers are doubtless aware by now that the entire "story" was a hoax from start to finish, pulled off by the author, as he states, to win a bet. The whole story is rather interesting reading and is a good illustration of how publications credit the appearance of news items appearing in other publications.

In this instance the *London Times*, *British Medical Journal*, *New York Times*, and *Literary Digest* were all taken in. That the purpose of the ruse was to sell a worthless book seems apparent. The author, like the passer of a bogus check, seems to have imposed upon the general faith in human integrity, which is at the basis of all commercial and professional activities. The excuse given that this performance was a joke does not excuse a professional man for such a performance, and we hope our friend, Banning, obtained all the notoriety he sought.

At the meeting of the Administrative Board of the Medical School, University of Minnesota, April 10, 1924, the following nominations for medical school appointments were made: A. G. Mulder for the Shevlin Fellowship, serving in Physiology; Frank J. Heck as Teaching Fellow in Pathology, subject to the approval of the Graduate Medical Committee; Dr. Thorald E. Davidson, first year Teaching Fellow in Surgery, subject to the approval of the Graduate Medical Committee; Dr. M. N. Moss as Assistant in Obstetrics and Gynecology; Dr. David M. Siperstein as Assistant in Pediatrics; Dr. Kenneth H. Sutherland as Assistant in Preventive Medicine and Public Health; Dr. Laurence H. Cady as Assistant in Preventive Medicine and Public Health; Dr. Hewitt B. Hannah as Assistant in Nervous and Mental Diseases; Dr. Aaron Friedell as Assistant in Pediatrics; Jean C. Hawley, Bertha E. Rich, Ada M. Olsen, Eva H. Burggren and Antoinette A. Proshok as Assistants in Nursing; Corah V. Lund and Marion M. Stewart as Instructors in Nursing; Dr. Harry DeWitt Lees as Instructor in Preventive Medicine and Public Health; Dr. Reuben A. Johnson as Instructor in Medicine; Dr. George N. Ruhberg as Instructor in Neurology; Dr. H. S. Lippman as Instructor in Pediatrics.

The following appeal (translated from the "Berliner Tageblatt" for January 8, 1924) has been issued by a committee composed of the following, and other well-known members of the medical profession: Professors Bier, Bunnn, Czerny, His and Goldschneider:

"The appalling need, which all brain workers in Germany are experiencing, is being felt in an overwhelming measure by doctors. Large numbers of people are no longer calling in medical aid on account of their inability to pay the fees. This dwindling number of their patients has brought thousands of doctors to such a dire state of need that they have been obliged to seek other ways of earning a livelihood, and the majority of them are in a pitiable condition. Some have been driven to commit suicide. This need might be mitigated, if in the already-existing or planned community kitchens in Berlin, meals for doctors—'mensæ medicæ' could be established. For these meals they should pay a small sum of money, or in certain exceptionally unfortunate cases, they might be given free. Dr. Eugenie Schwarzwald has placed at our disposal the kitchens which were created and are conducted by the Austrian 'Friendly Help.' What is now wanted is money for carrying on the work in the kitchens and for buying the food. We appeal to everyone who has cause for gratitude to the medical profession to send contributions to the credit of the 'Friendly Help' (Dept. Mensæ Medicæ) to the Bank of Mendelssohn & Co., Berlin, W 8, Jagerstrasse 51; and by this means assist in maintaining the public health."

NEW AND NON-OFFICIAL REMEDIES

The following articles have been accepted by the Council on Pharmacy and Chemistry:

PARKE, DAVIS AND CO.:

Apothesine

Apothesine Solution

Apothesine Hypodermic Tablets 0.08 Gm. (1¼ Gr.)

Apothesine and Adrenalin Hypodermic Tablets

Apothesine and Adrenalin Hypodermic Tablets (R "B")

Apothesine and Adrenalin Hypodermic Tablets Cylindrical (for pressure anesthesia)

Apothesine Ointment

Pituitrin "S" (Surgical)

E. R. SQUIBB AND SONS:

Cod Liver Oil-Squibb

UNITED STATES STANDARD PRODUCTS CO.:

Acne Vaccine

Gonococcus Vaccine

Pertussis (Whooping Cough) Vaccine

Staphylococcus Combined Vaccine

Streptococcus Vaccine

Typhoid Vaccine

Typhoid Paratyphoid Vaccine Combined

Acne Vaccine Combined

Normal Horse Serum

Diphtheria Antitoxin, Refined and Concentrated

Diphtheria Toxin-Antitoxin Mixture (0.1 L +)

Diphtheria Toxin for Schick Test and Control

Tetanus Antitoxin

TRUTH ABOUT MEDICINES

NEW AND NON-OFFICIAL REMEDIES

Patch's Flavored Cod Liver Oil.—Cod liver oil containing 0.5 per cent of essential oils as flavoring, and having a vitamin potency so that 0.002 gm. per day is adequate to promote the growth of young albino rats. For discussion of the actions and uses of cod liver oil, see Useful Drugs. The dose is not more than 4 c.c. (1 fluidrachm) 3 times a day. For children not more than 2 c.c. (30 minims) 3 times a day. E. L. Patch Co., Boston.

Vitalait Culture Bacillus Acidophilus.—A pure culture of *Bacillus acidophilus* in vials each containing about 7 c.c. It contains not less than three hundred million of viable organisms (*B. acidophilus*) per cubic centimeter at the time of sale. For a discussion of the actions and uses of cultures of *B. acidophilus*, see Lactic Acid-Producing Organisms and Preparations, Jour. A. M. A., Sept. 8, 1923, p. 831. The usual dosage is the contents of one vial diluted with water and followed by a quantity of sugar of milk. The culture is distributed by the manufacturer only and is sent by mail. The Vitalait Laboratory of California, Pasadena, Calif. (Jour. A. M. A., March 1, p. 717.)

Apothesine. — Diethyl-amino-propyl cinnamate-hydrochloride. Apothesine is a local anesthetic of the procaine rather than the cocaine type, that is, it belongs to that type which,

while effective for injection anesthesia (especially when combined with epinephrine), is relatively inefficient when applied to mucous membranes. It is rather slower in action than procaine. Its absolute toxicity is less than that of cocaine, but about twice that of procaine. It is employed for infiltration injection, nerve blocking, intraspinal injection, pressure anesthesia, oral administration as a palliative measure, for post-operative and persistent vomiting and pain of gastric ulcer. As a local anesthetic, apothesine is used in 0.5 to 2 per cent solution, generally with epinephrine and sterile water or physiological solution of sodium chloride. Apothesine is marketed in substance and also in the following forms: Apothesine solution 1.5 per cent; apothesine hypodermic tablets 0.08 gm.; apothesine and adrenalin hypodermic tablets (apothesine 0.04 gm.; adrenalin 0.00004 gm.); apothesine and adrenalin hypodermic tablets (apothesine 0.3 gm.; adrenalin 0.00003 gm.); apothesine and adrenalin hypodermic tablets cylindrical (apothesine 0.01 gm.; adrenalin 0.000025 gm.); apothesine ointment (apothesine 10 per cent; adrenalin 1:60,000, and menthol 0.5 per cent). Parke, Davis and Co., Detroit. (Jour. A. M. A., March 8, 1924, p. 793.)

Butesin Picrate. — Trinormalbutylparaminobenzoatedinitrophenal.—A compound consisting of one molecule of trinitrophenol (picric acid) and three molecules of normal butyl ester of 4-aminobenzoic acid. Butesin picrate combines the anesthetic action of butesin with the antiseptic properties of trinitrophenol (picric acid). An aqueous solution of 1:1,400 produces immediate and complete anesthesia of the eye, which lasts from ten to twenty minutes. Butesin picrate is used in the treatment of burns, ulcers and other denuded, painful lesions of the skin. For use, a 1 per cent butesin ointment is supplied by the manufacturer. The Abbott Laboratories, Chicago.

Normal Horse Serum.—A normal horse serum (see New and Non-official Remedies, 1923, p. 281) marketed in packages of one syringe containing 10 c.c.; also in packages of one syringe containing 20 c.c. United States Standard Products Co., Woodworth, Wis. (Jour. A. M. A., March 15, 1924, p. 876.)

Dibromin.—Dibromobarbituric acid.—Dibromin is an antiseptic and germicide proposed for use in solution as an irrigating fluid and wet dressings, for flushing cavities, irrigating infected wounds and for saturating gauze packings. Dibromin is claimed to be practically free from irritating or toxic properties in the concentrations required for therapeutic use. Solutions of 1:10,000 (6 grains to one gallon) or stronger are used. Dibromin is marketed in six grain capsules. Parke, Davis and Co., Detroit.

Acne Vaccine.—An acne vaccine (see New and Non-official Remedies, 1923, p. 302) marketed in packages of one 10 c.c. vial, each c.c. containing 40 million killed bacteria. United States Standard Products Co., Woodworth, Wis.

Gonococcus Vaccine.—A gonococcus vaccine (see New and Non-official Remedies, 1923, p. 304) marketed in packages of one 10 c.c. vial, each c.c. containing 1,000 million killed gonococci. United States Standard Products Co., Woodworth, Wis.

Pertussis (Whooping Cough) Vaccine.—A pertussis bacillus vaccine (see New and Non-official Remedies, 1923, p. 306) marketed in packages of one 10 c.c. vial, each c.c. containing 3,000 million killed pertussis bacilli. United States Standard Products Co., Woodworth, Wis.

Typhoid Vaccine.—A typhoid vaccine (see New and Non-official Remedies, 1923, p. 314) marketed in packages of three 1 c.c. vials, containing 500 million, 1,000 million and 1,000 million killed typhoid bacteria, respectively. United States Standard Products Co., Woodworth, Wis.

Typhoid Paratyphoid Vaccine (Combined).—A typhoid vaccine (see New and Non-official Remedies, 1923, p. 314) marketed in packages of three 1 c.c. vials, the first dose containing 500 million killed typhoid bacteria, 375 million killed paratyphoid A and 375 million killed paratyphoid B bacteria, the second and third doses each containing 1,000 million killed typhoid bacteria, 750 million killed paratyphoid A bacteria and 750 million killed paratyphoid B bacteria. United States Standard Products Co., Woodworth, Wis. (Jour. A. M. A., March 22, 1924, p. 967.)

Staphylococcus Combined Vaccine.—A staphylococcus vaccine (see New and Non-official Remedies, 1923, p. 310) marketed in packages of one 10 c.c. vial, each c.c. containing 1,000 million killed staphylococcus albus and 1,000 million killed staphylococcus aureus. United States Standard Products Co., Woodworth, Wis.

Streptococcus Vaccine.—A streptococcus vaccine (see New and Non-official Remedies, 1923, p. 312) marketed in packages of one 10 c.c. vial, each c.c. containing 400 million killed streptococci. United States Standard Products Co., Woodworth, Wis.

Acne Vaccine Combined.—A mixed bacterial vaccine (see New and Non-official Remedies, 1923, p. 318) marketed in packages containing one 10 c.c. vial, each c.c. containing 40 million killed acne bacilli and 1,000 million killed staphylococcus albus. United States Standard Products Co., Woodworth, Wis.

Diphtheria Antitoxin, Refined and Concentrated.—A refined and concentrated diphtheria antitoxin (see New and Non-official Remedies, 1923, p. 283) prepared according to a modification of Banzhaf's method, marketed in syringes containing 1,000, 3,000, 5,000, 10,000 and 20,000 units, respectively. United States Standard Products Co., Woodworth, Wis.

Diphtheria Toxin-Antitoxin Mixture, 0.1 L +.—A diphtheria toxin-antitoxin mixture (see New and Non-official Remedies, 1923, p. 284) each c.c. constituting a single dose and marketed in packages of 3 vials, each containing 1 c.c.; in packages of 30 vials, each containing 1 c.c.; and in packages of one vial containing 30 c.c. United States Standard Products Co., Woodworth, Wis.

Diphtheria Toxin for Shick Test and Control.—A diphtheria immunity test (see New and Non-official Remedies, 1923, p. 323) marketed in packages containing a vial with undiluted diphtheria toxin and physiological solution of sodium chloride for dilution. As a means of control there is also supplied diphtheria toxin which has been heated to destroy the exotoxins. The product is marketed in pack-

ages containing an amount sufficient for fifty tests; also in packages containing an amount sufficient for one hundred tests, but the strength of the toxin is such that the dose is 0.1 c.c. United States Standard Products Co., Woodworth, Wis.

Tetanus Antitoxin.—A concentrated tetanus antitoxin (see New and Non-official Remedies, 1923, p. 284) prepared according to the Banzhaf method. Marketed in syringes containing 1,500, 5,000 and 10,000 units. United States Standard Products Co., Woodworth, Wis. (Jour. A. M. A., March 29, 1924, p. 1047.)

PROPAGANDA FOR REFORM

Citrophan.—This is a "fat cure" exploited to the medical profession and the public by the Gotham Corporation, New York City. The only statement bearing on the identity of Citrophan which is made is the claim that it is "a new organic iodine compound." The claims made for Citrophan are many and various; back of all of them is the fundamental thesis: "Science has found that the chief cause of obesity lies in the development of alcohol in the digestive tract brought about by the action of yeast bacteria—taken into the stomach in improperly baked bread—and on raw fruits and vegetables." This claim is unsupported by scientific work. The A. M. A. Chemical Laboratory reports that Citrophan is sold in the form of tablets ranging in weight from about 4½ grains to more than 7 grains. Analysis indicated that the chief medicinal ingredient was tetraiodophenolphthalein. Sugar of milk, starch, vegetable tissue and traces of an acid-insoluble substance (probably talc) were found; also two per cent of an unidentified organic substance. Quantitative determinations showed the composition of Citrophan to be: tetraiodophenolphthalein 40 per cent, sugar of milk 52 per cent, ash (including talc) 3 per cent, starch and undetermined 5 per cent. About twenty-five years ago, tetraiodophenolphthalein, the chief medicinal ingredient of Citrophan, was exploited under the name "nosophen" as an external and internal antiseptic. It has never attracted much attention in this country. Fangerine is sold (in the form of tablets) along with Citrophan. This the A. M. A. Chemical Laboratory found to contain phenolphthalein as its medicinal ingredient. It is evident that Citrophan is not a new discovery as claimed, and there is no evidence that Citrophan will reduce weight, except perhaps by disturbing the digestive functions. (Jour. A. M. A., March 1, 1924, p. 734.)

Mistura Creosote Comp. (Killgore's) and Tablets Cascara Comp. (Killgore's).—The Council on Pharmacy and Chemistry reports that these products were found unacceptable for New and Non-official Remedies. Mistura Creosote Comp. (Killgore's) is marketed with the claim that each teaspoonful contains two minims of creosote "combined with Tonic Aromatics," but the identity and amount of the "Tonic Aromatics" is not declared. The Council declared the preparation in conflict with the rules that govern the acceptance of articles in that it is a mixture of semisecret composition which is marketed with unwarranted therapeutic claims and in a way that may lead the public to depend on it for the self-treatment of serious diseases. Tablets Cascara Comp. (Killgore's) are said to have the

following composition: "Ext. Cascara 2 grs.; Podophyllin $\frac{1}{8}$ gr.; Ext. Belladonna $\frac{1}{8}$ gr." The tablets were found in conflict with the rules that govern the acceptance of articles. The product is marketed under a name which is not descriptive of its composition in that the name indicates that it is a cascara preparation, yet the most active constituent is resin of podophyllum; the product is marketed with unwarranted therapeutic claims and the composition of the tablets is unscientific because there is no evidence that a therapeutic dose of extract of belladonna is useful with a suitable dose of resin of podophyllum or of extract of cascara sagrada. (Jour. A. M. A., March 8, 1924, p. 812.)

Sodium Morrhuate in Tuberculosis.—Sodium morrhuate is the sodium compound (soap) of the fatty acids obtained from cod liver oil. Its use in tuberculosis has been advocated, but like other preparations proposed for the treatment of this disease, it has not been shown to have value. The reported trials make its lack of value probable. Sodium morrhuate has not been admitted to New and Non-official Remedies. (Jour. A. M. A., 1924, p. 813.)

The Rectal Administration of Arsphenamin.—The intravenous administration of arsphenamin requires some skill, especially in children and in the obese in whom the veins are not readily accessible. Attempts have been made, therefore, to develop other methods of securing the effects of the drug. Among these, rectal administration has found most advocates. Manufacturers, ever seeking novelties, have used favorable reports to market suppositories of arsphenamin. In 1920, the Council on Pharmacy and Chemistry published a report on supsalsves stating that the evidence for the rectal administration of arsphenamin was distinctly unfavorable. At present the medical profession is being circularized by the Swan-Myer Company in an endeavor to popularize the rectal administration of arsphenamin in the form of suppositories sold as arsphenoids. It is opportune, therefore, that Littman and Hutton, at the request of the Therapeutic Research Committee of the Council on Pharmacy and Chemistry, present a critical review of the literature and the result of clinical trials of the rectal use of arsphenamin. Since most advocates of the rectal administration of arsphenamin stress its importance in the case of infants, the investigators carried out their study with children with active symptoms of congenital syphilis. They used arsphenamin given by enteroclysis and also the supsalsves suppositories. The authors conclude that the clinical results were too feeble as compared with the intravenous or intramuscular method to warrant favorable consideration of the rectal administration. The investigators hold, moreover, that neoarsphenamin and sulpharsphenamin are now generally used by the intramuscular route in the treatment of syphilis in infants with results that are above reproach. (Jour. A. M. A., March 15, 1924, p. 888.)

"Vita-Pep."—Vita-Pep is nominally put on the market by the Vitamine Products Co., of New York City, but actually seems to be put out by the Vitamin Food Co., Inc., of Westfield, Mass. The president of the Vitamin Food Co. is one Eugene Christian, who calls himself a food specialist. He has offered a "Course in Scientific Eating" in which

he showed his monumental ignorance of the subject he wanted to teach. Later, he was interested in an obesity treatment, the "Vaco Reducing Cup." Then he tried to sell oil stock to those on the sucker list. Then came the Vitamin Food Co., Inc., with Christian as president, and those on the sucker list were asked to buy stock in this company. In the earlier advertising, the product mainly stressed was "Vegex," which, according to the advertising matter, was a name that the Vitamin Food Co., Inc., had given to a British preparation sold across the water as "Marmite." Now comes the crowning achievement of the Vitamin Food Co., Inc., Vita-Pep. The circular for this contained the statement in large letters that the preparation contains alcohol 16 per cent. According to the label, Vita-Pep, in addition to containing wine with an alcohol strength of 16 per cent, also contains pepsin, rennin and a concentrate of vitamin "B." The advertising circular states that Vita-Pep is a "Zestful New Health Tonic" which "Restores Youthful Vitality." According to the advertising, "Vita-Pep is pleasant to the taste and delightful in its effect—takes away that tired, rundown feeling and makes one feel vigorous, healthy and strong." What is the United States Revenue Department going to do about it? (Jour. A. M. A., March 15, 1924, p. 907.)

Fat-Free Tincture of Digitalis.—Roth found that fat-free tinctures of digitalis had no advantages over the U. S. P. tincture of digitalis. On the contrary, he found some of these fat-free tinctures were so unstable that he advised manufacturers not to market them without stating the date of their manufacture on the label. "Fat-free" tincture of digitalis was introduced under the belief that the fat from the leaf produced gastric disturbance; but Hatcher and Eggleston fed the fat to cats and found that it had no emetic action whatever. After an investigation of the subject, the Council on Pharmacy and Chemistry concluded that there is no essential difference in action between "fat-free" tinctures of digitalis and the product official in the U. S. Pharmacopeia. (Jour. A. M. A., March 16, 1924, p. 911.)

Digifolin.—The claim is made for Digifolin that it keeps indefinitely. The available scientific evidence indicates that all digitalis preparations deteriorate with age. (Jour. A. M. A., March 15, 1924, p. 911.)

Canine Rabies Virus.—Results of the single injection method against rabies in dogs have been reported from different sources. The U. S. Bureau of Animal Industry has been conducting experimental work on this subject and results indicate that the prophylactic vaccination has value which, however, is determined to a certain extent by the virus to which the animal is exposed. The use of the single injection vaccine in animals that have been bitten is believed to be unwarranted at this time. The Högyes treatment of six doses, in animals bitten, has been used successfully for some time and the failures reported have been small. The use of the Högyes vaccine together with the cauterization of the wound and the placing of the animal in quarantine for six months to a year seems to be the best method of treating such cases. (Jour. A. M. A., March 29, 1924, p. 1066.)

Allonal-Roche.—Allonal (The Hoffmann-La Roche Chemical Works, New York) is "Allylisopropylbarbituric acid-Phenyl-dimethyl dimethylamino pyrazolon." In the literature first sent out, it was stated to be a "compound" made by "chemically uniting allyl-isopropylbarbituric acid (37.5%) with phenyl di-methyl-dimethylamino-pyrazolon (52.5%) amidopyrin, i. e., in molecular proportions 1:2." Examination of Allonal tablets made in the A. M. A. Chemical Laboratory last year showed that, in water, the substance behaved as a mixture of allyl-isopropyl barbituric acid and amidopyrin and not as a compound. Furthermore, the percentages of the ingredients given were not in accord with the statement that they were in molecular proportions. The published reports on its use are favorable, but they apparently include no observations with controls. The evidence thus far available does not seem to prove (1) that "Allonal" possesses advantage over a mixture of allyl-isopropyl barbituric acid and amidopyrin, or even over one or other of its ingredients alone; (2) that the administration of allyl-isopropyl barbituric acid and amidopyrin in fixed proportion is desirable. The product has not been accepted for New and Non-official Remedies. (Jour. A. M. A., March 29, p. 1066.)

PROCEEDINGS OF THE MINNESOTA ACADEMY OF MEDICINE

MEETING OF MARCH 12, 1924

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, March 12, 1924, at 8 p. m. The meeting was called to order by the President, Dr. Hamilton. There were 34 members and three visitors present.

The minutes of the February meeting were read and approved.

Dr. S. E. Sweitzer was elected to membership in the Academy.

The following members reported cases:

1. DR. E. M. HAMMES (St. Paul) reported three cases.

Case 1. Male, 19 years old, single, seen in consultation with Dr. Knox Bacon, Nov. 1, 1923. Family and personal history were negative. Present complaint began about October 10, 1923, with frontal headache. A few days later patient became nauseated with occasional expulsive vomiting. About Nov. 1st the family noticed that he had some difficulty in finding correct words while carrying on a conversation. At the same time he complained of vertigo on standing and of some impaired vision. In the course of a conversation he would stop abruptly in the middle of a sentence and forget to finish it. After being kept in bed for a week he seemed brighter and his headache was not as intense. He had an occasional degree of temperature. Pulse 80. Neurological examination at this time was negative except that he had bilateral choked discs, a slightly positive Romberg, and some mental confusion. His reflexes were normal. All laboratory findings, including spinal fluid examination, were negative except for a leuco-

cytosis of 12,000. I saw him again in consultation with Dr. Hoffman, November 15th. His condition was about the same but it was found that his choked discs were more pronounced; that he had right homonymous hemianopsia; some ataxia of the left arm; increased right knee-jerk; absent left abdominal reflex; slight tenderness in occipital region. X-ray of skull was negative. A diagnosis of left occipital lobe tumor was made. He went to Philadelphia and rapidly grew worse. Dr. Frazier suspected a possible occipital abscess and introduced a trocar into the occipital lobe, with negative findings. A bone-flap operation over the left occipital area revealed no definite pathology but Dr. Frazier thought that he probably had an infiltrating glioma of the left occipital lobe. He died three days later. No post-mortem was permitted.

Case 2. Female, aged 21, single, seen in consultation with Dr. A. Conley, of Cannon Falls, Minnesota. June 24, 1923.

Family and personal history negative. Patient states that during April, 1923, she developed headaches of short duration which gradually became more frequent and more severe. About one month later she had an occasional dizzy spell, especially when she became fatigued, and during the latter part of May she had three attacks of emesis in the early morning. About this time her headaches were relieved somewhat by getting glasses, but became more pronounced a week later. On June 19th her pulse was 75; on June 21st it was 50; on June 23rd it was 40 per minute, and on arrival at the hospital on June 24th her pulse was 36. She stood the trip (forty miles by auto) well.

Her neurological examination was negative except for slight rigidity of the neck muscles, which was probably voluntary, because of excruciating headache; an irregular nystagmoid movement of the eyeballs to the right; sluggish right superficial reflexes; a positive Kernig and absent kneejerks, and a beginning optic neuritis. A lumbar puncture was performed and about 35 c.c. of clear spinal fluid under pressure were removed. This gave some relief of her headache and her pulse went up to 48. The spinal fluid showed the following: Fibrin web on standing; 24 lymphocytes per cu. mm., a positive globulin, a negative Wassermann, and negative colloidal gold curve. No tubercle bacilli or other bacteria were found. A tentative diagnosis of tubercular meningitis or epidemic encephalitis was made. Her temperature was normal; her pulse varied between 36 and 70. With daily lumbar punctures, her headaches were relieved and she improved somewhat. However, on July 1st, she suddenly developed respiratory paralysis and died.

Post-mortem examination of the brain by Dr. J. C. McKinley revealed an internal hydrocephalus, and a tumor mass about 3.5 cm. in diameter entirely occluding the 4th ventricle. The tumor proved to be a sarcoma, probably arising from the choroid plexus. There were a few meningeal metastases but no pathology was found in the other organs.

Case 3. Female, aged 58, married. Seen in consultation with Dr. C. Bell, of St. Paul, October 30, 1923.

Her family history was negative; her past history was negative except that she had a carcinoma of the left breast removed in 1921 by Dr. Judd, of Rochester. About eight

months ago, she developed some pains in her back and in both legs, especially left ankle, which were thought to be rheumatic. About six months ago she noticed a small lump over the parietal region of her skull—painless and not tender. This grew quite rapidly but caused no inconvenience except that it was an annoyance when she combed her hair. By October it was about the size and shape of half of a hen's egg. October 30th she suddenly developed a generalized convulsion and when I saw her, half an hour later, she was quite confused but able to answer questions.

Neurological examination was negative throughout. During the night she had two more convulsions and the next day her right hand was weak and awkward. Her condition has slowly progressed during the past month. She furthermore has definite tenderness over the 4th and 5th lumbar vertebrae. An x-ray of the skull revealed multiple areas of bone destruction, probably carcinomatous metastasis. X-ray of left angle was negative.

2. DR. H. P. RITCHIE reported a case of Vesico-Diverticulo-Rectal Fistula.

Mr. C. E. B., aged 63, consulted Dr. A. MacLaren on February 12, 1923.

History: Fifteen years ago began to have frequency of urination; up three or four times at night for several years. Five years ago supposed to have had a prostatic abscess which discharged through rectum, followed by a urinary fistula. During this time several examinations were made and carcinoma of the prostate diagnosed by two reliable men. The fistula closed after three months. He has been able to do his work until a few months ago, when fistula returned.

Present complaint: Evacuation of urine every two hours per rectum. Small quantity of urine per urethram after great exertion. Patient losing weight with general physical lassitude.

Cystoscopy, made by Dr. Paul Cook, showed a suppurative cystitis. At right base of bladder was a large diverticulum, so placed as to be in line with the ureter. The right ureter could not be found. The left was catheterized to find pus urine but a competent kidney. There was little, if any, enlargement of the prostate.

Operation: The general conditions were most unfavorable for operative procedures, but the distressing state of the patient led him to assume all risks so Dr. MacLaren asked me to make the attempt at closure. From Dr. Cook's report it seemed necessary to locate the right ureter, so I cystoscoped him before attacking him from above, but was unable to find the meatus, nor at any time during the operation was the ureter seen. The extraordinary cystitis led me to attempt an extra-vesicle demonstration of the diverticulum, but such was the thickness and friability of the wall that the peritoneum was opened in two places before I desisted from this plan. The bladder was then opened, and the side wall bisected to and into the diverticulum. The fear was of making a large opening into the rectum, as it was natural to suppose that it was closely adherent to the pouch, but to the surprise and relief of Dr. Daugherty and myself a line of cleavage was readily shown so that the diverticulum was peeled off, like a skin from an orange, down to a point where we could see, by means of a head-

light and constant use of the aspirator, the fistulous track about one-fourth inch in diameter. This was clamped by forceps and tied, the sac removed, the wall of the bladder repaired, and drainage extra- and intra-vesicular instituted. As before stated, the meatus or ureter was never seen and from the location of the pouch and the extent of the dissection, it must have been involved. But so far as we could see there were no signs of kidney obstruction at any time.

The convalescence was stormy, caused by the most extreme sepsis of the wound, resulting from the great infection of the bladder, macroscopically due to the colon bacillus. The mercurochrome, now so widely advertised, seemed to give the best results in irrigating him.

After six weeks of trying time he recovered and within the past few months reports the fistula has remained closed but that frequency still is present. Occasionally there is some leak from the suprapubic wound. But the general condition is so improved as to be satisfactory to all concerned.

It would be hard to conceive of this situation occurring in a woman. It must be a most rare situation, but the possibility of its occurrence may make it worth recording.

3. DR. G. SCHWYZER (Minneapolis) reported a case of Adeno-Carcinoma of an Accessory Thyroid.

A fifty-four-year-old woman consulted us in the first week of January, 1924, for a tumor on the right side of her neck below the jaw.

There is an extensive scar in the region of the clavicles and upper end of sternum indicating a collar incision. We learn from the patient that she had a goiter operation three years previously. Following that operation she was hoarse, though her voice improved gradually but never completely. Six months following this goiter operation the present tumor made its first appearance in the size of a walnut, and it has gradually grown to the present size, that of a fist. The main distress through the tumor lies in the difficulty in swallowing food. The latter goes, as she says, to a certain point in her throat and only by a special effort is the food pressed farther down.

The rather well-nourished woman has not lost any weight, weighs at present 153 pounds, feels fairly strong and is able to do heavy work like washing and so on.

The tumor on the side of her neck is about four inches long and two inches in diameter vertically. The covering skin is normal, the consistency is generally soft elastic, partly fluctuating. It can be moved in a vertical sense, but not horizontally.

Laryngoscopically we find, and this has been confirmed by the laryngologist, an unusual picture. A tumor of the size of a plum bulges out into the pharynx below the tonsil and obstructs greatly the laryngoscopical picture. Only the left vocal cord is visible, and this appears paretic. Palpating this tumorous projection in the pharynx we are convinced that we have to do with the same growth that exists on the outside. We even state a feeling of fluctuation between inner and outer part of the tumor. The mucous lining covering the pharynx is normal. There are no pains by palpation.

Our diagnosis was a branchial tumor, partially cystic.

We operated January 10th under local anesthesia. We used 100 c.c. of 0.5 per cent novocaine solution. Anesthesia was done after Braun—prevertebral injection and blocking of the nerves around the tumor. Generally speaking the anesthesia was efficient. The operation was exceedingly difficult and involved unusual anatomical dissection. The nervus hypoglossus with its descending branches and the common carotid had to be dissected free from the tumor. The latter ran over the posterior part of the tumor but anteriorly. Inferiorly scar tissue made blunt dissection impossible. Posteriorly to the tumor lies the vertebral column, and between the two our hand tries to reach toward the pharynx. We are succeeding in peeling out the tumor away from the mucous lining of the pharynx, though the pharyngeal mucous lining tears in one place in a distance of about a half an inch. This rent is immediately sutured with chromic catgut. The wound is then closed and well drained.

Four hours after the operation the patient presents the picture of novocaine poisoning. She is stuporous, cyanosed in the face, has blue finger nails and an irregular pulse of only 70, breathing normal. We give 700 c.c. saline solution intravenously together with calcium chloride given by rectum in repeated doses so that she had about 8 grams that night. Sensorium becomes clear the next morning. She appears rather nervous. Continuous proctocleisis is given in order to avoid deglutition.

On the third day patient takes nourishments. On the fourth day foul breath is noticed. Patient becomes unmanageable, talks irrationally, gives the picture of persecution insanity, has to be isolated and restrained. The wound of neck discharges some infected secretion. Thorough disinfection—Di-chloramin-T used. We are probing the wound to see whether we have any communication between outer wound and pharynx. We are unable to feel the probe on the inside.

On the fifth day patient is comatose with a strong regular pulse of 120. She cannot be aroused any more and succumbed the morning of the sixth day following the operation.

The pathologist, Dr. E. T. Bell, reports that sections from tissue of the tumor show adeno-carcinoma of an accessory thyroid.

The case presents interesting features not only diagnostically and pathologically, but also post-operatively, on account of symptoms following local anesthesia. As I mentioned before, we used 100 c.c. of 0.5 per cent novocaine solution. In German literature I read of calcium chloride being given as an antidote for novocaine poisoning. It was rather astonishing to find the patient with a clear sensorium the next morning.

The question arose as to what this woman died from. The nearest reason we could think of was from infection due to the rent in the pharynx. In our estimation that rent opened up the day we noticed the foul breath. In regard to the psychical changes a thought of explanation came to us through the pathological report which told us that we had to do with an accessory thyroid. The other pathologist who examined the specimen thought he found tissue indicating hyperthyroidism. Clinically, however, the pa-

tient did not present any such symptoms previous to operation.

DISCUSSION

DR. FARR: I have had no experience with novocain poisoning because I have never seen anything more than slight manifestations of its toxicity. I would like to ask Dr. Schwyzer upon what he bases his diagnosis of novocain poisoning. When novocain comes in contact with the nerve cells and acts upon them the resulting substance formed is passive and innocuous. Toxic symptoms arise from the contact of novocain with the central nervous system. Considering my own experience, and just having completed the reading of Dr. Braun's book in which he goes into the question of toxicity extensively, I cannot believe that the symptoms given by Dr. Schwyzer are an evidence of novocain poisoning.

Poisoning as late as this does not occur, as far as I know. When the toxic dose is given symptoms appear immediately. I would, therefore, question symptoms coming on four hours after operation being due to novocain.

I have, in a few instances, accidentally injected a small amount of novocain solution directly into an artery or vein under circumstances which permitted the solution to be carried to the central nervous system. The symptoms were always acute and immediate. The patient develops a bursting headache, becomes pale, the pupils dilate, nausea and vomiting appear, and in case a lethal dose is given convulsions appear.

I have had a case of cocain death. The patient developed convulsions and a paralysis of respiration. The heart continued to beat for one hour and five minutes under artificial respiration. In this case we supposed we were using novocain. It would take more evidence than Dr. Schwyzer has given to convince me that the case he reported was one of novocain poisoning, and I believe we should be extremely careful in checking up such cases so that the actual toxicity of novocain may become known.

DR. G. SCHWYZER: In answer to Dr. Farr's remarks, I would like to say that the poisoning certainly followed the operation immediately, though I did not observe the patient for two to three hours directly after the operation. Still I positively know that four hours after the operation the patient was completely stuporous, could only be aroused by our shaking her and she was cyanosed at that time, her finger nails were black, and her former strong pulse weakened, decreased to only 70 and became very irregular. Of what other condition than of the poisoning through the local anesthetic could we think, when on the following morning we found the patient entirely clear, having a good expression, a free sensorium, and a strong pulse of 100?

4. DR. GEO. DOUGLAS LEAD reported a Case of Primary Tuberculosis of the Spleen with Polycythemia and Splenomegaly. Treated with Radium and Benzol.

The following case is reported to the Society because of its scientific importance and the long interval of time—nearly six and a half years—during which the patient was observed under treatment with radium and benzol.

SUMMARY OF CASE REPORT

Mrs. Van., American, age forty-nine. Married, four children, two living. First examination January 26, 1917.

Mother died of cancer of the stomach. One sister died of cancer of the uterus. Patient was said to have had "water diabetes" at three years of age. Had typhoid fever at eighteen years of age. Operated upon for appendicitis six years ago. For five or six years patient has occasionally taken antkamnia for headaches. Had menopause at forty-three years.

Patient's present illness dated back three years from the time of the primary examination. She complained of a feeling of tightness in the epigastrium, with excessive salivation and occasional vomiting spells. At first the attacks came only about once a month but increased in frequency and she has had as many as three a day, especially when under nervous strain. At that time patient also had dizzy spells and tired easily. Was bothered with morning headaches and attacks of epistaxis. Had lost in weight eighteen pounds. Never vomited blood. Redness of her face became noticeable two years before the primary examination. This was more marked under exertion.

Patient was a short, slim woman with light hair and eyes. One was struck at once by the deep red color of patient's skin and mucous membranes. The face, forehead and neck showed a high, dark red, while the fingers were red with a bluish tinge. The lips and alæ of the nose were a bluish tinge. The tongue was red with dilated veins on its under surface. The back of the throat was congested and covered with dilated venules. The inside of the lips and cheeks showed a dark red congested appearance. The eyes looked inflamed. The lids were red with prominent blood vessels over the sclera.

Careful physical examination was negative for organic disease outside of the enlarged spleen, the polycythemia, and the hypertension. The spleen could be felt two fingers' breadth below the costal margin. The surface was smooth, its edge hard and firm. The blood examination was as follows: Hemoglobin 140 per cent, R. B. C. 8,760,000, W. B. C. 13,500. Differential count: P. M. N. 77.0, Large monos. 4.0, Lympho. 12.5, Trans. 3.0, Eosin. 3.0, Basophiles 0.5, Myelocytes 0.0. The R. B. C. appeared normal in the stained smear. The blood pressure was 208 systolic and 110 diastolic. The von Pirquet tuberculin test was strongly positive. A test for the fragility of the red blood cells was normal. Phenolsulphonephthalein test was normal. Occult blood test for stools was negative. She gave a strong positive reaction to the subcutaneous tuberculin test.

All other findings being negative, a diagnosis of tuberculosis of the spleen, with polycythemia and hypertension, was made. The splenic area was exposed to 90 mgms. of radium on two successive days and patient was placed on benzol, five grains three times a day. Blood examination made seven weeks following the radium exposure was as follows: hemoglobin 110 per cent, R. B. C. 8,650,000, W. B. C. 7,300. Differential count: P. M. N. 81.0, Large monos. 1.0, Lympho. 16.5, Trans. 0.0, Eosino. 1.5, Baso. 0.0, Myelo. 0.0. Patient's color was much improved. Blood pressure was 130 systolic, 90 diastolic. Spleen was not palpable and was diminished in size to percussion. She had gained in weight but had had a hemorrhage from the bowels of one cup of blood five weeks prior to this examination.

Six months later patient was again examined. The blood

examination showed marked improvement—hemoglobin 105 per cent, R. B. C. 6,230,000, W. B. C. 12,800. Differential count: P. M. N. 75.5, Large monos. 3.0, Lympho. 15.0, Trans. 2.5, Eosino. 0.0, Baso. 0.0, Myelo. 0.0. The blood pressure was 148 systolic, 88 diastolic.

In November, 1919, about three years after coming under observation, patient was again examined. Her color was nearly normal. The spleen was not palpable at the costal margin. She had taken benzol from time to time. The blood examination showed the hemoglobin 110 per cent, R. B. C. 6,975,000, W. B. C. 10,750. Blood pressure was 136 systolic, 82 diastolic.

In April, 1920, patient returned again for bleeding of the gums when she cleaned her teeth. Blood examination showed more polycythemia—hemoglobin 125 per cent, R. B. C. 7,360,000. A second series of radium exposures of the spleen was made and patient was advised to again take benzol. Six months after the second radium treatment, the blood showed marked improvement and was as follows: Hemoglobin 100 per cent, R. B. C. 5,680,000, W. B. C. 17,000. Differential count: P. M. N. 79.0, Lympho. 11.0, Large monos. 5.0, Trans. 2.0, Eosino. 1.0, Baso. 2.0.

In May, 1921, patient was again examined, as she was feeling much worse. The color of her face was a dark, suffused red, the conjunctivæ very much injected and red. Her hands were a dark, bluish red color. The spleen, however, could not be palpated below the costal margin. Blood pressure was 175 systolic, 90 diastolic. The blood examination showed the hemoglobin 125 per cent, R. B. C. 7,760,000, W. B. C. 14,000. Patient was again placed upon benzol but made no improvement in the blood; in July, 1922, the blood examination being worse—hemoglobin 133 per cent, R. B. C. 9,190,000, W. B. C. 18,300.

Radium over the spleen was again used, 100 mgms. for eight hours being given. Patient improved symptomatically but no blood examination was made prior to September, 1923, when she returned again in another exacerbation, with a hemoglobin of 150 per cent, red cells 8,112,000, leucocytes 18,250. Radium 100 mgms. over an eight hour period was again used over the splenic area. No examinations of the blood have been made following the last radium treatment.

DISCUSSION

DR. ULRICH: I listened with great interest and some astonishment to the reading of this case, that is, a case of polycythemia associated with tuberculosis of the spleen. It has always been our assumption that tuberculosis of the spleen produces a profound anemia. Cirrhosis of the liver occasionally is associated with polycythemia but I have never heard of polycythemia associated with primary tuberculosis of the spleen. Primary tuberculosis of the spleen is exceedingly rare and the diagnosis can only be made with accuracy at the post-mortem or on biopsy. I do not think in this report that one can make a diagnosis of tuberculosis of the spleen by a von Pirquet reaction and subcutaneous tuberculin reaction. The cure of primary tuberculosis of the spleen is splenectomy.

DR. CROSS: I would like to ask Dr. Head whether the same clinical improvement followed the last use of radium, as it did in the other applications of it.

DR. MANN: I do not know very much about radium, but I would like to ask a question. As I understand it, the distance through which radium is effective is about 2 cm., when the hard rays are screened off, so in this case it could not shine into the spleen very far even if it could reach the spleen. Of course this patient was a slender woman. In that case, I would like to ask Dr. Head why he could not get a much better effect from x-ray, especially deep x-ray which would shine all the way through, if he did not want the spleen taken out.

DR. A. SCHWYZER: The hardest gamma rays are more penetrating than the hottest x-ray. It will penetrate 26½ cm. very well and go even through the body in a very large spleen. Radium will surely work. The filtering must be pretty strong. I remember a case I had in which we filtered through 1 mm. of brass, 0.5 mm. of silver, and in addition 2 mm. of lead. Of course lead gives strong beta rays and you have to use rubber over it. This spleen went down to one-third before we operated.

DR. HEAD (in closing): I can only say in answer to Dr. Mann's suggestion with relation to the penetration of radium, that the spleen diminished in size after the use of radium and the clinical evidence was very clear that the use of the radium had considerable to do with it. One of the interesting features about this case is that we did not apply it once but repeated the radium on three successive occasions, and to me that is fairly good evidence that it was the radium which produced the favorable outcome.

In answer to Dr. Cross' question, the last exposure has been too recent to determine whether or not it will be of any real benefit. In the next to the last exposure I do not think we got as profound an effect. At the present time the patient's blood is as polycythemic as at any time.

I was in hopes that in the discussion the natural exacerbations of the disease might be brought out. That is, do the cases, like pernicious anemia, run courses with exacerbations and remissions when left to themselves? In the literature one finds very few reports of cases of polycythemia that have been followed over any long period of years to determine just the course which they pursue, uninfluenced by drugs or other management. Osler had cases reported over a number of years.

In answer to Dr. Ulrich's expressed doubt relative to the etiological relationship between tuberculosis and polycythemia: If I remember correctly, one of the first cases on record was proven at autopsy to be tuberculosis of the spleen. In Weber's monograph on polycythemia, the detailed report of the authentic cases which he presents reveals tuberculosis as a prominent pathological factor in the history of the cases and the autopsy findings. Tuberculosis of the spleen has been established by numerous case reports as associated with polycythemia and splenomegaly. I think if Dr. Ulrich will read Weber's and Winternitz's studies, he will change his notions regarding the independence of tuberculosis of the spleen and polycythemia.

Of course I do not want to contend that the subcutaneous tuberculin test, or a positive von Pirquet test is proof of tuberculosis of the spleen. I think, however, that with the clinical absence of tuberculosis or other disease in other organs and the presence of the positive tuberculin tests,

there was justified the assumption that we have a true case of primary tuberculosis of the spleen with polycythemia in this case. At least I would stand for that diagnosis until some other could be proved.

This case is of a good deal of interest scientifically for the reason that we have been able to watch a real case of polycythemia vera, probably proven to be of tuberculous origin, over six years of time, through three distinct exacerbations, and been able to watch the profound effect, on the blood and the size of the spleen, which radium produced with the use of benzol. My own clinical opinion is that we have received more benefit from the radium than the benzol. I have now under observation a man forty years of age, with polycythemia and enlarged spleen, who about two months ago vomited a bowlful of blood. This patient gives a four plus Wassermann and the diagnosis of syphilis of the spleen seems justified. In these two cases we have, therefore, polycythemia with splenomegaly caused by two of the great contenders for pathological honors, the tubercle bacillus and the spirochete of syphilis.

5. DR. J. G. CROSS reported the following case: This case is reported because of the great difficulty in making a diagnosis. The patient was a man of 64, weighing in health 190 pounds, a lawyer by profession. With the exception of a so-called "nervous breakdown" many years ago and a suspicion of tuberculosis as a young man, his history to July, 1923, is practically that of a healthy man. At that time he showed retention of urine and a prostatic enlargement was made out and operation advised by his physicians, Dr. Staples and Dr. Butler. Prostatectomy was done at Rochester in two stages and he returned home to Minneapolis in early November, 1923. Except for the presence of some albumin and pus in the urine as is common in such cases, his recovery seemed to be very good, and he resumed the practice of his profession.

The first week in January he attended the annual stag dinner given by one of his friends, at which such delicacies as pork sausages, sauerkraut, and buckwheat cakes were partaken of. He had some immediate distress—nausea and vomiting. He was seen about three days later because the vomiting did not cease. His temperature was 99.2 and as a matter of fact, never was raised to 100. Pulse rate 80 to 90, respiration normal. He complained of the nausea, and slight pain in the left loin extending around toward the back, at times beyond the posterior axillary line. There were no masses in the abdomen and a marked absence of any tender points. Bowel movements were easily induced with enema, and the urine contained, as above stated, pus and albumin, but no sugar and no casts. The stools were entirely negative, and especially I wish to emphasize the fact that at no time was fat or fatty acids present in the stool, nor was glycosuria ever found, though the urine was tested almost daily during the entire illness.

Blood examination showed 5,400,000 red cells, hemoglobin 80 to 85, white cells 23,000 to 24,160, with 88 per cent p. m. n., 12 per cent lymphocytes (5 small and 7 large), blood chemistry January 21st showed urea nitrogen 28.50, creatinin 1.88.

On account of persistent nausea no examination of the stomach with barium could be done. Fluoroscopy of the

chest, afterwards corroborated by roentgenography, gave very dense mediastinal shadows almost obliterating the left border of the heart, and extending above and to the outside of the aortic arch, as well as to the right of the heart strip on the other side. These shadows did not pulsate, and on account of their density were assumed to be probably due to new growths. At no time were there any symptoms referable to the chest except a temporary pleuritic pain on the left side, for which nothing could be found at autopsy.

On account of the absence of fever, the persistence of nausea and vomiting, the leukocytosis together with the x-ray picture in the chest, it seemed most likely even in the absence of a mass in the abdomen that the patient was suffering from new growth in the stomach and mediastinum. Death occurred on February 7th from asthenia.

Omitting the details unessential to the diagnosis, the autopsy findings were as follows:

The abdomen contains only a very small amount of clear fluid. The appendix is long, thin and adherent behind the cecum. It has the consistency of a fibrous cord. There are old fibrous bands between the gallbladder and the hepatic flexure of the colon, and the colon and duodenum. The omentum is adherent to the left costal margin.

The heart showed some degenerative changes but no gross valvular lesions. Coronaries not narrow. The lungs are light. No palpable nodules.

The liver weighed 2,140 grams. The cut surface showing very definite yellowish tinge. The gallbladder is dilated but not thickened, and there are no calculi in the cavity. The ducts are patent.

The stomach. There are no lesions of the mucous membranes. A semi-fluctuant mass protrudes into the fundus a short distance outside the stomach. No lesions are found anywhere in the gastrointestinal tract.

On cutting through the foramen of Winslow, cloudy fluid, similar to that previously mentioned, appears, but not in marked quantity. On separating the colon a cavity is entered which is at first thought to be the cavity of the stomach but it proves to be the markedly thickened lesser peritoneal cavity filled with cloudy fluid. In the posterior wall of this cavity is seen a yellowish necrotic mass about 2 cm. in diameter. Later investigation shows that this is necrotic pancreatic tissue. To the right of this necrotic mass is a small rounded cavity which on probing is found to lead to the foramen of Winslow. This channel is about 1 cm. in diameter. On following up the pancreatic duct from the ampulla it is found to lead to a necrotic mass about 3 cm. in diameter, involving the tail of the pancreas, and with necrosis extending into the lesser peritoneal cavity. In the adipose tissue about the pancreas, small yellowish nodules are found which grossly strongly suggest fat necroses. The semi-fluctuant mass near the cardiac end of the stomach is found to be an extra-gastric collection of fluid with fat necrosis in its wall.

The genital tract showed no gross changes except the operation scars and a rim of prostatic tissue, the mass of it representing about one-third that of an average prostate. In this is a cavity about 1 cm. in diameter and irregular in outline.

The lymph nodes at the bifurcation of the trachea are

moderately enlarged and show much coal pigment but in a few of them grayish white translucent areas are present, the largest of these measuring about 1 cm. in diameter and somewhat suggestive of tumor, although they may be hyperplastic lymphoid tissue. No lesions in the pre-aortic or pelvic lymph nodes. Marked enlargement of lymph nodes at the bifurcation of the trachea.

Microscopic examination showed marked tubular injury and arteriosclerotic change in the kidney. Prostate: no evidence of malignancy. Tracheobronchial lymph node: marked hyperplasia with necrosis but no evidence of carcinoma. Pancreas: extensive acute and chronic changes, the acute changes being ante-mortem necrosis with extensive leucocytic infiltration about these necroses, the chronic change being marked inter- and intralobular fibrosis.

DIAGNOSES

1. Suppurative pancreatitis.
2. Cloudy swelling of myocardium with epicardial petechial hemorrhages.
3. Fatty liver.

It will be seen that there are interesting features to this case from both the diagnostic and pathologic viewpoints. I believe it is safe to say that his condition was impossible to diagnose clinically. There was nothing in the physical examination, his symptoms, nor the laboratory findings which would lead one to look for a lesion in the pancreas. His presenting trouble was the constant nausea and persistent vomiting with increase of his white blood cells and absence of fever. It was evident at autopsy that there was enough functioning pancreas left to explain why there was no free fat in his stools, nor sugar in his urine.

A little later another patient was seen with a very much distended abdomen, absence of fever, and pain which prevented his lying down. This had been present only a few days. Previous health had been unusually good. The man, about 60 years old, was in active business life. The pain was epigastric. There was some vomiting but not persistent. There was almost no rise of temperature, but a white blood count between 18,000 and 20,000. In the region of the gallbladder there was a palpable mass somewhat tender to touch. In the epigastrium a tumor could be palpated, but its form and size were difficult to make out.

The abdomen was very tense like that found in serositis of the liver ascites. However, the dullness to percussion was entirely left-sided. The urine was sugar free. X-ray of the stomach showed a peculiar shape—a sort of teapot dome effect—in that the prepyloric antrum was narrowed to the size of a thumb for a distance from three to four inches. Gastric analysis was negative, free fat being found in the stools. Consultation with the surgeon was urged on the ground that surgical exploration of the pancreas should not be longer delayed. I will ask Dr. Mann to speak of this case from the surgical side, as he operated upon him.

DISCUSSION

DR. MANN: On examination this man presented two masses which could be felt. One, a low bulging mass in the epigastrium, and the other a sort of roughened mass in the gallbladder region but a little outside of that region. His symptoms were centered about the center of the ab-

domen; the pain was constant and rather intense. Having seen a few cases of pancreatic cyst and knowing that is about the only thing which presents a tumor which can be seen or felt in the epigastrium, I made a diagnosis of pancreatic cyst (provisional). At operation a mass presented exactly where the pancreas would be, about half the size of a croquet ball, rounded on one side, and at one point did have a cyst about the size of a large marble, so my diagnosis checked up with that in a small way. I made a small opening into this mass and we got some lobulated material from 1 cm. to 2 cm. long about the consistency of oysters, but did not get very much of it. On microscopic examination that proved to be lymphosarcoma. The mass on the left side of the liver was rolled up omentum.

This man stood the operation very well. He died today, over four weeks after his operation. He has had no pain since the operation. I presume it was the tension on that capsule which caused the pain.

The x-rays were as Dr. Cross has stated, and the diagnosis of the roentgenologist was carcinoma of the stomach, which we rather doubted. I presume a sarcoma of the retroperitoneal lymph glands beginning probably in some gland close in near the head of the pancreas.

DR. HEAD: I would like to ask Dr. Cross two questions. First, in the first case reported, did the man show evidence of profound prostration or exhaustion indicative of a serious organic condition, or did the clinical picture present more of a toxic state? Second, how long from the onset of the symptoms was it before the patient died?

DR. CROSS (in closing): It is hard to tell just when this

process started. I imagine that the stag dinner furnished the stimulus, after which things eventuated rather rapidly, but that he had the beginnings of this process in the pancreas for some time before. Of course that is speculation. The stag dinner took place on the 5th of January; I saw him on the 9th, and he died on February 7th. He was not markedly prostrated.

I want to mention the fact again that leucocytosis without fever was present in both of these cases. In the one case the pancreas was five or six times as large as a normal pancreas. There was almost no free fluid in the abdomen, and the distension of the abdomen was due to the increased size of the pancreas. I should be very suspicious again with a leucocytosis of 24,000 and absence of fever.

He was not prostrated, but he was nauseated almost continuously. There was no mass to be felt anywhere. He had pleuritic pain for a few days.

Another case of pancreatitis had exactly the same pain, but higher up. It might have been described in the same terms that one would describe splenic infarct.

He presented no symptoms of obstruction of the bowel; never had any difficulty with bowel movements.

6. DR. A. SCHWYZER showed several x-ray films of a case of empyema following pneumonia in a boy 11 years of age. Trocar and cannula were inserted and the cavity Dakinized.

The meeting adjourned.

JOHN E. HYNES,
Secretary.

BOOK REVIEWS

BOOKS RECEIVED FOR REVIEW

THE ANTIDIABETIC FUNCTIONS OF THE PANCREAS AND THE SUCCESSFUL ISOLATION OF THE ANTIDIABETIC HORMONE—INSULIN. J. J. R. MacLeod, Prof. of Physiology, University of Toronto, and F. G. Banting, Research Professor, University of Toronto. Series No. 2. 69 pages. Illus. St. Louis: C. V. Mosby Co., 1923. Cloth, \$1.50.

METHODS IN MODERN MEDICINE. The Manual of the Medical Service of George Dock, M.D., Sc.D. George R. Herrmann, M.D., Ph.D., Instructor in Medicine, University of Michigan. 521 pages. Illus. St. Louis: C. V. Mosby Co., 1924.

SOCIAL CONTROL OF THE FEEBLEMINDED. A Study of Social Programs and Attitudes in Relation to the Problems of Mental Deficiency. Stanley P. Davies, Ph.D., Exec. Secy. Committee on Mental Hygiene, New York State Charities Aid Association. 207 pages. New York: The National Committee for Mental Hygiene, Inc., 370 Seventh Avenue, 1923. Paper, \$1.25.

"OBSTETRICS FOR NURSES." Charles B. Reed, M.D., St. Louis, C. V. Mosby Co. Second Edition, 1923. Price, \$3.50.

So many of the present-day books intended for the in-

struction of the nurse-in-training and for the guidance of the post-graduate obstetric nurse, seem to the reviewer to have as their greatest aim the teaching of the scientific and theoretical phase (thus almost obscuring the more important practical side of the subject), that it is a great pleasure to him to read one that departs from the usual.

Such a book is Reed's "Obstetrics for Nurses" which is now in its second edition. In its 390 pages of text, this little book covers in a very satisfactory way all that the nurse who wishes to make obstetric-nursing her specialty, needs to master of the anatomy and physiology of the female generative organs, including pre-natal, lying-in, and post-partum care. The dietion is throughout clear and concise and the one hundred and forty-four illustrations are for the most part well chosen. There are twenty-five chapters in all, the last seven taking up Care of the Child, Cleanliness and Sterilization, Diets, and a Therapeutic Index with an appended glossary of more or less special terms and phrases.

In the first thirty-six pages there is given an easily understandable discussion of the anatomy and physiology of the pelvic organs with special emphasis on their relation to normal pregnancy. Next, there are four chapters on abnormal, as well as normal, pregnancy, including the Hygiene of Normal Pregnancy, a chapter that could well be read with benefit by every practitioner, reflecting as it does the present-day sound, common-sense ideas on this

subject. Following in orderly arrangement are three chapters dealing with normal labor, its course, mechanism and the nurse's duties throughout its conduct, both in the home and in the hospital. The normal puerperium is next considered in detail, and thereafter are seven chapters on the abnormalities and complications of labor and the puerperium, including one on Infections and one on Minor Operations (special technique for the nurse).

All in all, Dr. Reed's "Obstetrics for Nurses" is a distinct improvement over the usual style of books intended for a like purpose and which are so frequently mere abridged editions of the larger text-books on obstetrics. It is above all practical and the nurse who studies with it as her guide will, I am sure, be more than ever a valuable and efficient assistant to the obstetrician.

ROGER S. COUNTRYMAN, M.D.

MENTAL DISORDERS. An Introduction to the Study of Mental Disorders. By Francis M. Barnes, Jr., M.A., M.D., Associate Professor of Nervous and Mental Diseases in the St. Louis University Medical School, Neurologist to St. Mary's Hospital, Consultant Neurologist to St. John's Hospital, Consultant Psychiatrist to the St. Louis City Sanitarium, Consultant Neuropsychiatrist to the U. S. Veterans' Bureau, Ninth District, St. Louis. Second Edition. C. V. Mosby Company, St. Louis, 1923.

The purpose is to give in brief outline the important features of some of the more common types of mental diseases; the groups considered are ones presented before fourth year students' clinics. The second edition was prepared, the author states, in response to the request from teachers that the notes be made available to other students than those in Dr. Barnes' classes.

More than half the book consists of a historical introduction that is very interesting and instructive and of a discussion of various psychological features concerned in mental processes.

Part II discusses briefly various common types of psychoses, together with a discussion of psychoneuroses and defective states.

The author states that it has not been his purpose to write a complete treatise on psychiatry but to place in students' hands a brief outline of fundamentals of psychiatry.

It is written in an interesting manner and each chapter is complete in itself so that it may be used readily. It will be found of interest to those whose work is limited to psychiatry and of help not only to the undergraduate student but to the practitioner who wishes something covering the field of psychiatry that is not too exhaustive.

EDWARD J. ENGBERG.

GRADUATE NURSE and Trained Laboratory Technician wishes position in town of 20,000 or more. Over two years' experience. Good references. Address B85, care of MINNESOTA MEDICINE.

FOR SALE—\$8,000 general practice in modern town, 1,000. Good roads, good schools, live town, prosperous dairy country. Collections 95 per cent. Wish to sell modern home and interest in small hospital. No other surgeon to hospital nor in adjoining towns. Specializing. Any reasonable terms. Address B87, care of MINNESOTA MEDICINE.

FOR SALE—To close an estate, good location for practice in St. Paul. No other physician in same vicinity. Excellent opportunity; will bear close investigation. Address B75, care of MINNESOTA MEDICINE.

FOR RENT—During mornings, exceptionally desirable office furnished for doctor. Reasonable. 341 La Salle Bldg., Minneapolis, Minn.

MINNEAPOLIS OFFICE SPACE TO SUBLET—Very desirable office space at 323 La Salle Bldg., Minneapolis, to be sublet by Drs. Willson, Cabot and Wohlrabe. For information call at office or telephone Main 3220.
